In entering on this subject it will be convenient to premise that the real question at issue may be considered under the following heads :—1. Whether inventions should be encouraged and inventors rewarded. 2. Whether any more practicable means of encouraging inventions and rewarding inventors exist than a system of patents. 3. The best means of creating and protecting such property. No one, to my knowledge, has yet advanced so far in liberalism as regards the rights of property or the encouragement of inventions, as to deny or seriously dispute all those propositions. Such heresy, so to speak, has not broken out into open flame, however it may be smouldering, and appear to be involved in the ashes of doctrines which have occasionally been announced, or underlie the surface of opinions which have been advanced, and will come under discussion on the present occasion. The President of the British Association (Sir W. Armstrong), at Newcastle, and your Chairman of Council (Mr. Hawes), in the paper already referred to, give expression to the opinion that the seeds of invention strewn broadcast over the world by the previous investigations of learned men, are published and given to the world, ready to germinate in due season whenever the occasion or necessity may arise, and that legislative interference will neither produce them nor stimulate their growth. This opinion, proceeding from, or endorsed by, such authority has been, and will be, often quoted as condemnatory of all views favourable to property in invention, and in support of the views that invention does not require the stimulus of the reward or remuneration which the Patent Laws are designed to confer. From these premises it is contended that new processes or new mechanical contrivances, derived from information thus freely and gratuitously published, are public property, and cannot belong to those who merely give such knowledge a practical form. But is not this to beg the whole question? Is there not also some confusion arising from the use or imperfection of language? Is a proper distinction always maintained between discovery and invention in reference to these questions? A law of nature, as gravitation, or a machine, as the steam-engine, or a process, as vulcanising, are spoken of indifferently as discoveries or inventions. This confusion of language is fruitful of difficulty in the subject under consideration. We speak of discovering a law of nature, as gravitation, cohesion, elasticity, attraction, heat, atomic theory, equal transmission of pressure in fluids, elastic and inelastic; we discover (Fr. *découvrir*) that which has a prior or actual existence in nature; we do not invent such law. In the proper sense of the term, invention is more in the nature of creation than of discovery. We invent or find out a mode of doing, that is, of producing a particular thing; every new manufacture is in that sense a creation. To call it a discovery is to introduce a confusion in the use and application of terms; or, to add one further illustration, we speak of the discovery of vaccination and of the invention of the penny postage, neither of which could be the subject of the patent laws. The inventor applies the laws of nature; invention consists in the application of such laws. For instance, Watt's invention of the steam-engine was an application of the laws of heat; Dollond's achromatic object-glass, of the laws of light; Wollaston's camera-lucida, of the laws of refraction and total reflection. Vulcanised rubber was a new creation; such a thing had never existed before, the invention consisting in the application of heat and sulphur to rubber under certain conditions. Photography was an invention in the strict sense of the term; *i.e.*, a picture so produced was a new creation, a new manufacture. The self-acting mule, the product of the genius of Richard Roberts, whose loss we so recently have had occasion to deplore, the regenerative furnace of Siemens, the automatic self-recording telegraph, the last production of Professor Wheatstone, the various forms of telegraph or telegraphic cables may with propriety be called new creations, or, in the language of the Patent Law, new manufactures. Seeing, then, that invention consists in the application of the laws of nature to the matter provided to our hands, in giving to such laws a practical form, how can it be said that property cannot be acquired in the application of knowledge given to the public? That is the very foundation of the system. The distinction above adverted to is more important than may at first sight appear. The correct and appropriate use of terms is a matter at all times deserving consideration, but especially so when it is the foundation of distinctions in reference to the subject under consideration. Thus, for example, M. Legrand, insisting on the distinction between patent right and copyright, on the incontestible difference between the work of the writer or author of a literary composition and the inventor, says, "If Masillon had not written '*Le Petit Carême*,' no other person could have done it. If, on the contrary, Niepce had not discovered photography, some one else would have invented it. What do we say? Another has invented it. Daguerre has had the same idea. Artists really create something; they produce work which no other would have produced. In the domain of industry, on the contrary, the inventor is not, properly speaking, any more the creator than he could be the exclusive possessor. He finds; he discovers; but he does not create."* The confusion of the above needs little comment; an idea not carried out is no invention. It is matter of law that a patent cannot be granted for a principle or an idea, but only for its application or embodiment; thus there could be no patent for the discovery of a law of nature or property of matter, unless applied or embodied in a manufacture. In litigated cases, the question whether the subject of the patent is a principle or a manufacture not unfrequently arises. The following observations of a highly scientific and most learned man, Mr. Baron Alderson, are worthy of special attention: "I have always thought that the real test was this, that in order to discover whether it is a good or a bad patent, you should consider that what you cannot take out a patent for must be considered to have been invented *pro bono publico*—that is to say, the principle must be considered as having had an anterior existence before the patent. Now supposing in Watt's case it had been known that to condense in a separate vessel was a mode of saving fuel, then Watt certainly could have taken out a patent for carrying into effect that principle by a particular machine; but then his patent would have been for a machine; and if I invented a better machine for carrying out the principle, I should not infringe his patent unless my machine was a colourable imitation."

The distinction now insisted on is little regarded by many who speak of patenting ideas and principles, and derive an argument from the abuse rather than the use of the system, and assume that to be part of the system which by law is illegal.

But it is said that inventors need no such encouragement, that invention is a real pleasure; that true inventive genius labours on involuntarily; that the glory of a great name or the possible reward of a grateful nation is a sufficient stimulus; that the philosopher, physician, and chemist give their results to the public, who appreciate originality of mind, and do not fail to reward it. All this may be true, but it applies to the labourer in the field of discovery rather than invention. I remember on one occasion, at a meeting at Manchester, when this doctrine was propounded, that Richard Roberts replied: "The patterns of that particular invention cost me £500; they would have been 'colted' (that is, copied) the next day but for the Patent Laws." The gratitude of the public is soon exhausted when the benefit is reduced into possession.

However great may be the stimulus of the pleasure of invention, the advocates of this view would appear to lose sight of or disregard the fact that the invention and the public require adaptation to each other; that the introduction of an invention involving any material change is a constant struggle with the existing state of things, and in a large class of cases is as much an education as the training and introduction of a child; that it is a contest with existing practice, in which contest the inventor has to struggle with all the prejudices, capital, and influence of the existing trade and established manufacture. The history of the struggles of the introduction of new invention, as detailed on the hearings before the Judicial Committee of the Privy Council in cases of application for the extension of the

* See "The Patent Question," p. 17, by R. A. Macfie, papers at Edinburgh Meeting of Social Science, 1863.

terms of patents, can hardly fail to produce the conviction that these struggles would never have been undergone but for the expectation of the reward. Many inventions are wholly in advance of the age, and would fall still-born but for the return anticipated on the capital embarked in their introduction. There was, it is said, no patent for paper (A.D. 1200), or for oil (1297), or for glass (1300), or for the mariner's compass (1302), or for printing (1430), or for gunpowder (1450), or for many other useful inventions of world-wide utility, and therefore it is left to be inferred that encouragement to invention or reward to the inventor in the nature of the patent system is unnecessary. Until the wants of mankind or the isolated efforts of mighty minds in the progress of civilization had formed the alphabet, so to speak, or laid the foundation of practical arts, there was nothing out of or upon which the superstructure could be raised. Because skins or the hand-made fabric once served for clothing, can it be contended that the progress of industry and of the practical arts has not been most materially stimulated by the expectation, however delusive, of reward and pecuniary remuneration?

Books were compiled and written before and without any copyright laws, but does any one adduce this as an argument against the justice or expediency of these laws, the analogy of which to the patent laws can hardly be denied, notwithstanding the distinctions which may be drawn between them? It is said that things belonging to the province of copyright are an embodiment of the individual mind, which no other mind would have made, whereas things belonging to the province of patent right are capable of being made by many minds, of being originated in the same identical form by a plurality of persons—that the inventor has, in fact, only forstalled time, and that it may be presumed that the invention would have been made at some time by some other person, and would certainly have been made so soon as the want should arise—that to infringe copyright is slavishly to imitate, whereas patent right may be infringed without such imitation. The subject of copyright is one specific combination of words, letters, and lines, in this respect similar or analogous to the specific combination constituting a machine, or to elements arranged in a certain order, whereas in many cases inventions may be exhibited in various material forms, carrying out or subservient to one leading idea. Different minds do not hit on the same means for carrying out the same idea or of attaining the same object. Invention is one continuous process of simplification, as the history of invention clearly shows. In cases of copyright the identification is easy, speaking to the eye or the ear, whereas in cases of patent right the identification is sometimes difficult, inasmuch as, to the eye, the material forms may be different. These distinctions point only to the difficulties of the subject, and must be dealt with accordingly; but the principle of property in both is the same, namely, a recognition of right in the product of the brain, as embodied in a material form. Invention being one continual progression, each stage in advance of the preceding cannot fail, in many cases, to provoke the opposition of the capitalist, who may look with little favour on the changes which a great improvement necessitates; his old mill may have to be refilled with new machinery. Again, the capitalist in mind who can devise an expedient for overcoming any difficulty so soon as it arrives, may not be pleased by finding that he has been forestalled by some other person; that he must respect the property which the law gives to possession, and adopt some other, and perhaps inferior, means of attaining the same end, or come to terms with the owner of that property. Hence, patents have been called obstructive, likened to toll-bars on the highway. Authentic instances of such obstruction would be a great boon, and contribute much to the history of the subject; they have been often asked for, very few have ever been even pointed at. If such exist to the extent contended for, or to any extent, the remedy is very simple—make a license under a patent a matter of compulsory purchase, to be settled by arbitration on a review of all the circumstances of the case. If the owner of land or houses has to restore to the public a portion of the ancestral property acquired from the public in former times, there can be no great injustice in requiring a patentee, on fair and proper terms, to admit others to share in that which he may be regarded as having acquired from the public; in this sense that same other person, it may be presumed, would have made the invention when the emergency arose. The patent might be granted on this express condition, and the effect of such a system immediately tried. But philanthropic and moral considerations are introduced. The system is denounced as a lottery, and injurious to the personal interests of the inventor, who rarely obtains the reward which he expects, or to which he may be fairly entitled. Is this not part of the lottery of life? The race is not always to the swift, nor the battle to the strong. The very objection assumes an expenditure of time, labour, and money in producing a result beneficial to the public, though not to the individual author. Let such an individual be rewarded out of the "Inventors' Fee Fund," the surplus fund to which he has contributed. Let this blot be removed. Let it not be said that a great benefactor to the public has been unrewarded, when ample funds exist of the inventor's own creation, out of which he may be amply compensated. Let it not be said that the name of one of our greatest inventors, just removed from amongst us—Richard Roberts—should be without a national tribute for the emancipation and development of industry, of which the self-acting mule was the pioneer, or that the family of the man should be permitted to want in the midst of the untold millions which his inventions have added to individual and national wealth.

But the principle of patents is said to be inconsistent with the principles of free trade. Here, again, I cannot but think there is some misconception and confusion in the use of language. The theory of the patent law is the creation of a trade, or, as expressed in one of the earliest reported cases, "when any man, by his own charge and industry, or by his own wit or invention, doth bring any new trade into the realm, or any engine tending to the furtherance of a trade that never was used before, and that for the good of the realm the king may grant him a monopoly patent for some reasonable time, until the subjects may learn the same, in consideration of the good that he doth bring to the commonwealth, otherwise not."* It has been said that these principles are not now applicable, that all trades are established, and that the reason does not apply, there being no necessity for the instruction; but such an observation is made regardless of the fact that knowledge and invention are progressive; that if there be not the same ignorance as in bygone centuries, there is a special opposition, which our very civilization has created, rendering the special property in an invention the best means hitherto desired, if not the only means, for ensuring that progress which all profess to desire. It may then be assumed that new trades, or improvements in existing trades—which, for the question under consideration, may be regarded as new trades—are still to be created, and that it is the object of the patent laws to foster inventions constituting such new trade. The fostering care of special property in the invention is continued only for a limited and reasonable period, until the trade shall have been established; during that period the particular trade is not to be practised or special property shared without its owner participating in the proceeds; when that period has expired the trade, whether established or not, is open to all, with this further advantage, that a description of the manner of practising the invention is open to all; the requirement of such a description—called the specification—having been substituted in the reign of Queen Anne, in lieu of a proviso appearing in some private acts for patents requiring the patentee, during the latter half of the term granted, to take apprentices and teach them the knowledge and mystery of the said new invention.†

The principles of free trade can have no application to a trade which is non-existent, or which has to be created. If, as the theory assumes, special property in an invention be essential or materially conducive to the creation of the trade, to prohibit such property is to prevent or delay the establishment of the trade. The supporters of this objection would appear to confound patents for inventions with the exclusive privileges declared to be illegal by the Statute of Monopolies (21 Jac. I., c. 3, A.D. 1624). It is contrary to the principles of free trade to restrain any person from, or subject him to a tax for practising, any existing trade as a baker or brewer, or buying and selling in the cheapest market, but it can hardly be said to be contrary to the principles of free trade to give exclusive privileges for the creation of that which does not exist, for a trade to become free as soon as established.

The real question would appear to be as to the terms or conditions upon which such privileges should be granted, and not to the principle of such privileges. If patents are granted improvidently, there is an abuse of the system; remove the abuse, but do not found on the abuse an argument against the use of a system, unless such abuse is incurable and inevitable.

The abolition or diminution of secret practices, with their long train of attendant evils, has frequently been relied on as an argument in support of the patent system; and the freedom with which the knowledge of inventions is now given to the world has been relied upon as one of the great improvements due to the passing of the "Patent Law Amendment Act, 1852." This, however, in the able paper of the chairman of your council on the economical effect of the patent laws, is objected to as inducing the circulation all over the world of the best possible descriptions of our most recent improvements for the benefit of our rivals. Is this generosity really detrimental to our national interests? Can any well-authenticated instances of that detriment be adduced? Isolated cases may exist in which some particular interest may, under special circumstances and for a limited time, be prejudiced. This is a practical test, and capable of proof; and if it should appear that in some few cases the result may be that the foreign manufacturer, by means of such information, may be enabled to compete successfully with the home manufacturer, either at home or in the markets of the world, are not the compensating advantages such as greatly to outweigh or overbalance the supposed detriment? Is such detriment in any respect comparable to the evils of the secret system of the guilds of our forefathers, when art was a mystery and trade a protected monopoly?

Are not the objections, when thoroughly examined, directed to the administration rather than to the principle of the system? Is not the proper course to reform the system—at least to make the attempt?

Time will not permit me to pursue this part of the subject in detail on the present occasion; it may be sufficient to point to the proposals which have been made for removing or mitigating the admitted evils of the present system, and which may be classed as follows:—

1. That patents should not be granted as of course, but that some check should be placed on their indiscriminate issue by a preliminary inquiry and report, by which the applicant would receive the benefit of the accumulated experience of the office of the Commissioners of Patents in consideration of the fees paid.

2. That the validity and infringement of patents should be tried by a

* See 1 Webster, "Patent Cases," p. 6.

† See Act for Bank's Invention, A.D. 1651, c. 2; 1 Webster, "Patent Cases," p. 28.

judge, assisted by two or more assessors conversant with the subject selected by the parties or by the judge, from a panel provided for the purpose.

3. That the owner of a patent should be required to grant licenses, or to sell the whole right for the benefit of the public, on adequate consideration.

4. That the fees paid on patents should constitute an "Inventors' Fee Fund," to be applied wholly to inventors' purposes, to the reward of meritorious inventors, to the repurchase of patent rights, and the advance of practical science.

TELEGRAPHIC NEWS.

The Brett Collection.—The sale of this recherché collection of works of art and objects of vertu realized the handsome sum of £13,000.

United Kingdom Electric Telegraph Company (Limited).—This company announce that they have now opened their lines to Edinburgh and Leith. Messages of twenty words 1s. between any of the company's stations.

Presentation.—A very handsome and valuable gold watch has been presented to J. R. France, Esq., Acting Engineer to the Submarine Telegraph Company, by the Directors of the Steam Tug Company, as a recognition of his gentlemanly and courteous conduct while engaged in restoring the submarine cables in the German Ocean.

Mr. Reis' Acoustic Telephone.—It has long been known that a magnetic current will produce a sound in wires of iron and other metal. Mr. Reis takes up this fact, and has constructed an acoustic telegraph or telephone, an instrument which delivers a message by sounds of different pitch. As yet it is far from perfect, and to many ears there is no perceptible difference in the tones, but as the possibility of communicating between different places by sounds has been demonstrated, we may expect to hear again of the subject.

East Indian Railway Company.—By the thirty-fifth report of the directors of the East Indian Railway Company, it appears that the electric telegraph is now in working order from the Kurrumnassa to the office in the Lelinghur, at Delhi—a distance, with branches, equal to 556 miles. There are 45 stations at work, from which the number of messages sent amounted to 124,878 as against 106,050 in the previous half-year; the receipts from private messages amounting to Rs. 8,935 3a. as compared with Rs. 5,969 1a. in the previous half-year. The laying of two additional wires, making four in all, has been commenced from the Kurrumnassa. The telegraph has been worked very satisfactorily.

Iron and its Appliances.—Professor Fairbairn, in a recent lecture on this subject, at the Dumfries Mechanics' Institute, thus referred to the manufacture and laying of submarine telegraph cables:—"If a heavy weight were suspended to a piece of the cable, the copper wire, which is exceedingly ductile, would be drawn out; the gutta-percha covering would also expand; but on the removal of the weight, the insulator, being elastic, would contract, but the copper wire would not go back: the result of which was, that the contractile force of the gutta-percha had a tendency to double up the wire, and push it through the insulator: so that when the cable was being paid out there was the risk, wherever the cable came in contact with the water, of the electric current passing into the sea, and the wire thus becoming useless. This showed how very cautious and careful they should be in the construction of such cables, in order to see that any part of the cable when put to a severe strain should harmonize with the other parts of it."

Auckland.—The *New Zealander*, of the 30th January, states that the extension of the electric telegraph to Ngarawahia was progressing rapidly, and that already the line had reached Koheroa, and would in a few days be completed as far as Meremere. Strong covering parties were employed for the safety of the workmen engaged.

The New Zealand papers received by the last mail state that the materials required for the completion of the electric telegraph between Invercargill and Bluff Harbour, Southland, had been received; and that, under the chief superintendence of Mr. Weldon, the inspector of telegraphs, the line had been very speedily placed in working order, and messages have been since regularly transmitted between Invercargill and the Bluff. The convenience to the commercial interest had been found to be very great, and the extension of the line was likely to take place very shortly. The instruments for the line were supplied by Messrs. Siemens, Halske, & Co., of London.

New Zealand.—The *Lyttleton Times*, with respect to the extension of the telegraph to India, viâ the Persian Gulf, observes:—"We cannot be otherwise than deeply interested in the success of the expedition, for at any rate the Indian telegraph is of the greatest importance to these colonies. Amongst the objects contemplated is the immediate restoration of communication between Batavia and Singapore; and it is expected that the Dutch Government will construct or subsidize a line to Ceopang, in the island of Timor. From this point we may look forward for telegraphic communication to this continent at no distant day. Already the South Australians are pushing forward to colonize Arnheim's Land, as, and from Queensland, a route is opening up for stock along the Gulf of Carpentaria. It will remain with ourselves in a great degree to take early advantage of such an event; at any rate, we may be sure that an overland line will soon bring these southern communities into the great Indian submarine route."

The following notice has appeared in the daily papers:—"Challenge to Bonelli's Telegraph Company.—Had the challenge from the United Kingdom Telegraph Company to test the relative merits of Hughes's and Bonelli's systems of telegraphy been fairly made, the directors having at once accepted it, would have awaited the result without further action. But the evident animus of its contents, the repetition of the advertisement long after acceptance, and the statements it contained, are so calculated to mislead, that they feel bound to give them an unqualified contradiction; they, therefore, append the following extracts; and, appealing from the assertions of a company, whose very existence is threatened by the establishment of a sixpenny rate for messages, to the opinions of men of highest authority, who have tested the system, leave the issue to the public. The United Kingdom Company state that Bonelli's system is slower, more costly, and impracticable, carefully shunning correctness, in which Hughes' is so deficient and Bonelli's so perfect. That it is practicable, is proved by the fact that the system has been at work between Liverpool and Manchester since September last, without a single interruption from weather or electrical causes. Mr. Fleeming Jenkin says: 'It is more rapid than any other printing arrangement with which I am acquainted—except, perhaps, Caselli's. Bonelli's system can, in my opinion, be profitably and economically worked under good management.' Mr. Henley says: 'I have carefully examined Bonelli's printing telegraph, working between Manchester and Liverpool. I consider it decidedly the best type printing telegraph yet invented, very simple in its construction, there being a total absence of complicated machinery, and not liable to the errors (caused by wrong letters being printed) which so frequently occur in other type printers, and which, from the little reliance to be placed on them, has prevented them from being used.'"

Cape of Good Hope Telegraph Company.—At the ordinary general meeting of the shareholders in this company, held on the 27th inst. at their offices, 25, Poultry, Mr. J. A. Radecliffe in the chair, the report was unanimously adopted. It stated that the cable had been well and substantially laid by the contractor, and had recently been opened. They could not say much for the traffic at present, because it had been opened so recently; but from what they had seen of it, they were quite satisfied it would prove remunerative to the shareholders. They had made arrangements with the Electric and International Telegraph Company, by which messages would be received at any of their stations in the United Kingdom for the Cape. The retiring auditors were re-elected, and £10 awarded to each for their services.

The Electric Telegraph and the Railway System.—It was stated that 27 per cent. of the accidents in England were due to the want of the telegraph. As all the Indian railways had telegraphs, this per centage might be assumed to be erased from their quota of casualties. It would appear from the parliamentary returns, that out of 4,225,240 passengers carried in India during the year 1860, none had been killed from causes beyond their own control, while 94 per million only were injured. On comparing this with the English returns, it appeared that out of an annual average of 139,000,000 passengers carried, 15 per million were killed, while 319 were injured. According to the returns for 1862 the passengers carried were 173,721,238, while the number killed were 26 per million, and 450 per million received injury. It also appears that one-half of the accidents on the English lines arose from collisions, while on the Indian railroads one-seventh only emanated from the same cause. This proved that collisions which might be looked upon as preventible accidents, to a certain extent, were less frequent in India, and necessarily so, owing to the aid afforded by the electric telegraph in regulating the traffic.

The Atlantic Telegraph.—The failures of science, to paraphrase an old proverb, are the renewal of scientific endeavour. When the electric cable between Great Britain and America was *not* laid, the certainty that it must be laid, at some period more or less remote, was then apparent to all who have any faith in human energy and human skill. Every disaster in the course of that great experiment of 1858 was a priceless lesson to the men of thought and enterprise who seek to achieve the same magnificent project in 1864. They recommence their task with an improved knowledge of its conditions and its difficulties; and a comparison of the old and the new cable will show that this knowledge has not been acquired in vain. Mr. Cyrus Field, who has crossed the Atlantic Ocean thirty-one times in the service of the company by whom the vast undertaking is to be carried out, has perfect confidence in the efficiency of all the plans; and even an unscientific observer must be impressed with the fact that all the grave objections to preceding modes of operation have been practically met, and, to all appearance, overcome. On the 28th instant a large party of gentlemen, who regard with peculiar interest the proceedings of the Atlantic Telegraph Company, met at the Gutta-Percha Works in Wharf-road, City-road, and witnessed every separate process of manufacturing and testing the cable. There were present, among many others of note, the Marquis of Tweeddale, Mr. Bright, M.P., the Hon. W. M. Evarts, Mr. Percy Salmon, Mr. Saward, Captain Hamilton, Mr. Glass, Mr. Varley, Mr. Edwards, and Professor Wheatstone. The electrical tests incidental to the operations of isolating the wire were conducted with great nicety, and with admirable effect. Fusees were fired by means of a current despatched through sixty miles of the coated wire, and various pretty results were shown, such as would have made the dullest lecture attractive to the least scientific hearer. One young gentleman of an ingenious countenance and an inquiring spirit manifested an obliging readiness in touching a spring which communicated with a

battery, so as to discharge the explosive compound at the farther end of the wire. The manufacture of the cable differed at almost every step from the process adopted six years ago. It is nearly twice the size to begin with, and the weight of the copper strand which forms the conductor is considerably more than doubled, the number of pounds avoirdupois to the nautical mile being 300 to 107. The insulation is rendered perfect by means of a new adhesive material—Chatterton's compound—with which the copper strand is first coated, and which alternates with the successive layers of gutta percha, binding them firmly together, and effectually excluding air. A transverse section of the wire and its fourfold skin exhibits the dark rings of the cementing compound, and, so far as isolating protection is concerned, justifies an implicit belief. But protection against rough external influences is also needed, and still more requisite is the strength of resistance which provides against an enormous tension. In place, then, of the eighteen strands of charcoal-iron wire laid spirally round the core, with a padding of tar-saturated hemp between, we have now ten solid wires of homogeneous iron, each wire surrounded separately with five strands of Manilla yarn, saturated with a preservative compound, and the whole laid spirally around the core, which latter is padded with ordinary hemp, steeped with preservative mixture. The breaking strain of the old cable was 3 tons 5 cwt.; while in the present case it is 7 tons 15 cwt. So much for the increased strength of the coil; and in other essential respects great improvement has been attained. The splicing is now managed with a certainty which insures not only a greater power of resistance in the joints than in any other part, but also an equal electrical strength throughout. The contract with Messrs. Glass, Elliot, & Co., for the manufacture of this cable extends, we believe, to the laying it down; and the accomplishment of their immense work may be looked forward to with as much hope as anxiety.—*Daily Telegraph.*

MISCELLANEA.

This is the age of inventions; Mr. Barker, our countryman, to whom the organ owes the lightening of the touch of its key-board by aid of the pneumatic lever, now associated with M. Verschneider, having been commissioned to build an organ for the church of Augustin, at Paris, intends to introduce there another new device, in which by aid of electricity the communication of key with pipe, at present a cumbrous and complicated piece of business, is replaced by something simpler.

Freaks of Lightning.—In a house at Felzius, near Figeal, struck with lightning, the flooring of the upper story was turned upside down, and all the nails disappeared; all the locks and bolts were destroyed, and there remains nothing of the lock-press, which was in one of the rooms. The owner of the house was in the act of unlocking the outside door at the time, and the key in his hand was cut in two by the lightning without causing him any injury.

Seeing the Elephant.—Some years ago there was a joke passing around upon the different telegraph lines, which was played off upon a good many unsuspecting individuals in the following manner:—"Boston, April 1st, 1855.—To L. E. Phant, at some Hotel, New Bedford: In leaving this morning, you neglected to take your trunk. What shall be done with it?—Adam Goodsell." By pronouncing the name of the party addressed quickly, and the signature slowly, a solution of the "sell" is obtained, and you get a view of the elephant at the same time.—*Prescott.*

How to Begin.—Too many are, however, impatient of results; they are not satisfied to begin where their fathers did, but where they left off; they think to enjoy the fruits of industry without working for them; they cannot wait for the results of labour and application, but forestall them by too early indulgence. A worthy Scotch couple, when asked how their son had broken down so early in life, gave the following explanation:—"When we began life together we worked hard, and lived upon porridge and such like, gradually adding to our comforts as our means improved, until we were able at length to dine off a bit of roast meat, and sometimes a boilt chuckie (or fowl); but as for Jock, our son, he began where we had left off—*he began with chuckie first.*" The same illustration will apply to higher conditions of life than that of this humble pair.

The Earth.—M. Gavarret gives the following explanation of the manner in which the earth acts when forming part of a circuit:—"The poles of a battery, when disconnected, have equal and contrary tensions. When insulated conductors are placed in contact with them, they themselves become the poles of the battery, the battery having furnished a current sufficient to charge them, but not of sufficient duration to move a galvanometer needle. If the conductors are enlarged, the time occupied in charging them will increase, until, as they are still further enlarged, a limit will be reached at which the flow of electricity into them will last long enough to affect the galvanometer; and when the conductors become infinitely long or infinitely large, the time occupied in charging them also becomes infinite; or, in other words, the current will pass precisely as if the poles were connected. Thus, when the extremities of a circuit are connected to the earth, which is an infinitely large conductor, their respective tensions are diffused in all directions, without producing any appreciable tension in the earth itself, so that the current will continue to flow.—*Télégraphie Electrique.*

Atmospheric Electricity.—There is always free electricity in the air and in the clouds, acting by induction upon the earth and the wires, and creating an opposite tension in them. If the electrical state of the atmosphere were constant, that of the wires would remain constant also, as far as regarded their mutual influence. But it is not so. When an electrified cloud approaches the wires, it causes currents in them which escape in sparks at the apparatus, demagnetising or reversing the magnets or fusing the coils, even although there may be no actual lightning. No case has, however, occurred in which the person in charge of the apparatus has been injured, for the instrument affords the current a much more ready path than that given by the human body. Tying a knot in the fine wire of a coil will often cause the spark to jump to the metal frame, and thus preserve the coil from destruction. During a storm the instruments should be placed on short circuit, by connecting their terminals across; and, if the lightning be very vivid, it may be best to disconnect them, putting the line direct to earth. In situations much exposed to lightning, some form of paratonnere or protector should be used, especially at the end of long pieces of underground work or cables. But they must always be placed indoors, or it will be impossible to preserve their insulation. As long magnets retain their power much better than short ones, it is desirable not to use very short needles in signal instruments, where reversals might be dangerous.—*R. S. Culley's Hand-book of Practical Telegraphy.*

PRICES CURRENT OF INSULATING MATERIAL.

Gutta Percha, as imported.

Genuine, fine and good	2/2 to 2/6 per lb.
Good re-boiled	1/6 to 1/8 „

India Rubber.

Para, first quality	1/10 to 1/11 „
second „	1/7 to 1/8 „
third Negro-head	1/2 to 1/3 „

BONELLI'S TELEGRAPH.

In our last number reference was made to a challenge on the part of the United Kingdom Telegraph Company to the Bonelli Telegraph Company, to test the relative merits of the Hughes and Bonelli's systems of telegraphy. Having been informed that the trial was to take place on the 30th of April, we, at some inconvenience and trouble, went down to Liverpool to witness the competition. On our arrival we, however, found that the United Kingdom Telegraph Company had, for reasons which will be found in another part of this journal, declined the contest. Several experiments were, nevertheless, made with the Bonelli instrument on that day and the following Monday, with the results hereafter described. The Bonelli Company have for some time, as our readers are aware, carried on an extensive and increasing business between Liverpool and Manchester, and have recently determined to greatly extend their operations, and with that view have applied for additional capital, which we believe has now been secured. The Company in the first instance will proceed to construct a line between London and Glasgow. Having no interest in either Company more than that of public journalists, we shall endeavour to place before our readers the facts as they presented themselves to us, avoiding technical expressions or scientific terms, which have unfortunately rendered the science of telegraphy unintelligible but to a few.

Although we have before described in our columns the construction and action of Chevalier Bonelli's instrument, for the benefit of recent subscribers we shall place before them again a short description thereof.

Let the reader suppose himself to be the operator: before him he will find an oak table, 7 feet in length, 17 to 18 inches wide; along the centre of this table runs a miniature railway, terminated at either end by a spring buffer, and spanned midway by a kind of bridge, 6 inches in height, and 2½ or 3 inches wide. Upon this railway is placed a species of waggon, 3 feet long and 5 inches wide, 3½ inches in height, running upon four brass wheels; on the surface of this waggon are two long rectilinear openings—the one occupying the upper half, and destined to carry the message which is to be sent, the other occupying the lower half, and intended for the message, which may be to be received; upon the bridge are two small metal combs, each containing a number of insulated teeth, answering in number to, and connected with, the insulated conductors of which the line is formed. The combs differ from one another—the one which is to despatch the message being formed of so many teeth, having a certain freedom of action, is on the side of the bridge farthest from the operator; the other, or writing comb, is formed of a similar number of teeth fixed in a block of ivory, and forms a perfect line, which rests with a slight but regular pressure transversely on the paper, and occupies the nearer portion of the said bridge. We will suppose that the tables have been tested, and that a number of messages are to be despatched; these messages are distributed to a given number of compositors, who set them up in ordinary type with great rapidity, and handed to the operator, whose waggon has already been pushed to the upper end of the rail, and is held there by a simple catch; he places this dispatch in the opening destined for it, and in the second opening he places a plate of metal, upon which has been laid thirty or forty strips of paper prepared with a solution of nitrate of manganese; this done, he turns a small handle and watches; if the operator at the other end has done his work, the waggon is at once freed from the catch, and is set in motion by a simple weight, the pace being regulated by a fan; the type of which we have spoken is thus brought under the action of the despatching comb, and runs lightly under its teeth from end to end; one half of the journey being made, the writing comb comes in contact with the prepared paper. If the operator at the other end has had a message to send it will have been printed in clear, legible characters, of a deep brown colour, answering with unerring fidelity to the forms over which the corresponding type comb has passed, while the operator (the reader) learns that *his* message has as surely been received; the message is stripped off, the waggon remounted, the type box changed, and the process of transmission and reception repeated.

On the day appointed for the competitive trial we attended at the Company's office in Dale-street, Liverpool. There were present the Mayor of the town, several other gentlemen, and the representatives of the press. The Company stopped the general traffic at one o'clock, when the experiments commenced.

Upon testing the line wires for insulation or loss of current with one of Mr. W. T. Henley's galvanometers and an ordinary sulphate battery of 48 elements, we found that the leakage or loss on each was as follows:—On No. 1 wire, 55°; on No. 2 wire 35°; on No. 3 wire, 40°; on No. 4 wire, 10°; on No. 5 wire, 55°. Although the state of insulation on the wires varied, especially in the case of No. 4 wire, we could not detect any difference in the strength of the current from its action on the prepared paper—the decomposition as indicated by the colour was as complete on the *point* of No. 5 wire as it was on that of No. 4. This is an important feature in the working of this ingenious instrument, and from which we may infer that distance or heavy leakages have not the same disadvantageous effects upon the decomposing powers of a current, as they have upon its directive and magnetising properties, upon one or other of which, with a few exceptions, depends the action of every instrument hitherto introduced.

We have given above the measurements of the leakage on the wires before commencing the experiments; the following are the measurements, taken with the same instruments and the same battery power immediately on the completion of the experiments:—No. 1 wire, 15°, No. 2 wire, 0°, No. 3 wire, 0°, No. 4 wire, 7°, No. 5 wire, 45°. Yet with this superior insulation we could not find any marked difference in the impressions of the metallic points on the prepared paper. The five wires appeared to have conveyed the same amount of decomposing or printing power.

The instruments employed on the occasion had been in daily operation for some months. In the time-tests the first message or matter was sent at 11 minutes to 2 o'clock p.m., and the last at 2 minutes to 2 o'clock, p.m. The number of messages sent and received between Liverpool and London, in nine minutes, being 80, containing on an average from 20 to 22 words, or altogether of from 1,600 to 1,760 words, consisting of some 8,800 letters, in the whole of which there was not a single error. A far greater amount of matter could have been sent had it not been for the absence, through severe illness, of the clerk who has had the management of the instrument. We found that the five young ladies employed were greatly in advance of the instrument with their type-sticks, or rulers, owing to the absence of

the regular manipulator from the Liverpool station, as above mentioned.

On the following Monday we again attended at the Company's offices, in Manchester, it having rained heavily the previous day and night. On that morning we witnessed the transmission of numerous messages to and from Manchester, with the same satisfactory result as on Saturday, which was a dry and sunny day; in fact we found that the letters were more distinctly rendered under circumstances which have a contrary effect on the operations of instruments depending upon the action of the electro-magnet, and not upon the decomposing powers of the current.

Nothing could be more satisfactory than the operations carried on in our presence, and we believe that the instrument, not only from the wonderful rapidity with which communication is effected by its means, but from the correctness of its action and its non-liability to get out of order, will prove the most valuable hitherto introduced; and after the opportunity afforded us to witness the apparatus in full operations, over a distance of 46 miles, of which 8 miles are underground wires, we feel certain that the expense of the five wires necessary is vastly more than compensated by the immense quantity of work which it is capable of accomplishing.

We witnessed with admiration the rapidity with which the five fair compositors performed their respective duties; the time occupied in setting the type for messages of from 20 to 25 words seldom exceeding 85 seconds, and this with the capability of the instrument to transmit the messages at the rate of 50 words, or 250 letters, per 10 seconds, does not certainly indicate that either commercial or mechanical impracticability will ever militate against the extensive employment of the instrument for telegraphic purposes.

One of the great advantages possessed by the Bonelli instrument is that the message can be repeated to any extent when once the type is set, and that it can be sent to any number of towns by an ingenious system of shunting; for instance, a message of say twenty words is printed at Manchester, instantly upon its completion the five wires are united by switches to the five wires leading thence to the Liverpool, York, or Glasgow instrument, when the message is reproduced without the necessity of the re-setting the type at any intermediate station. As a further illustration of the advantages which such a system of telegraphing affords, let us suppose that an important speech is being delivered at the House of Commons, or elsewhere, a transcript of the short-hand notes is delivered to the compositors, the matter is placed in the machine, and at the distant towns duplicate copies can be produced in "print" and sent to as many papers as there might be published in those towns, at the rate of 200 words per minute, as effected in our presence.

THE DOMESTIC TELEGRAPH.

THE following useful and amusing article was recently contributed to *Chambers's Journal* by a gentleman well known in the telegraphic world, and needs no further introduction to our columns:—

If any person in the present day were to announce that he purposed making use of a gravity-pump, to pump weight out of himself, and then to project himself, for a few days' shooting, into Africa, he would probably be regarded, by even enthusiasts, as an insane individual. If, however, any person living in 1763 had given notice that he purposed employing a small portion of lightning to carry a message for him from England to Russia, he also would then have been looked upon as a no less deluded maniac.

It is an interesting, and, at the same time, an instructive study, to watch how the impossible gradually become the probable, the probable the actual, and, soon after, a thing that everybody knows. When we become familiarised with any great or important discovery, and with its application to every-day life, we soon forget, or rarely reflect upon the trials and difficulties that truth has invariably to encounter before it takes its place in its new phase as one of the facts of the day.

Even in the present day, when steam and electricity, glass and gunpowder, and many other useful agents are familiar to us all, there are not many amongst us, who, if suddenly transplanted to a colony, or amongst people who were utterly unacquainted with these things, could either clearly explain matters connected with them, or instruct others how to use them.

Steam and its applications are not nearly so mysterious to the public generally, however, as is electricity in all its branches. Even to those who have studied the subject all their lives, electricity is still a mystery. We live in an epoch of names, and when we have applied a term to anything we seem to have described its meanings or attributes; but we are as far as ever from a real knowledge of this force or power, when we state it is called electricity, from *electron*, a Greek word signifying amber, and is produced in various ways, friction being one.

In order, however, to be fully aware how many persons there are who still remain unacquainted with even the simple application of electricity, it is necessary to be in a measure behind the scenes, in which position we ourselves have had the advantage of hearing very many amusing incidents.

It is not by any means uncommon to find that, some parcel being required in a hurry, a frantic individual rushes into a telegraph-office, and requests that his parcel may be sent by telegraph immediately. Within the last few days, a gentleman seriously requested a telegraph-clerk to send two dozen stamps to his wife in the country, the stamps being offered and folded up in readiness for transmission. Another person being desirous of sending an anonymous message to a friend, refused to write his message on the paper, because, should he do so, his friend would of course recognise the handwriting. Not long since, we heard a facetious young gentleman inform two or three individuals that the Americans had lately discovered so rapid a means of photographing as to enable them to photograph the messages as they went along the wire. The information was not only seriously received, but one of the hearers stated that he had read something about it in the papers, and it was called "Topping the Telegraph."

When any little incidents of this nature happen, it is not unusual to attribute them to "old ladies;" but, with one or two exceptions, the most amusing misunderstandings have occurred, not with ancient dames, but with gentlemen in the full bloom of health, and not past the middle age.

One of the many singular facts that are brought to light by the telegraph is, that certain types of minds instinctively connect haste with danger or disaster. It was not many years ago that it was considered dangerous to travel from York to London under two days. The telegraph, then, which is a very hurrying sort of affair, would, we can easily imagine, create a certain amount of alarm from its speed alone; but, in addition to this, it was, when first used, a very expensive way of sending intelligence, and employed therefore only in extreme cases. Hence the public, to a certain extent, have been trained to connect a telegraphic message with sudden illness, accidents, want of a doctor, fires, or some disaster; and, to those whose lives jog on in a slow every-day style, a telegraphic message is so unusual an event, that they are probably correct when they connect a telegraphic message with alarming news. Though the establishment of a London district-telegraph has to some extent done away with these ideas, there yet lingers a large remnant of this alarm, which crops out on many occasions.

Not long since, the District Telegraph Company considered it advisable to send out a few circulars informing the public that the could now procure one hundred of their stamps for one pound; that a stamp placed on a written message, which might be enclosed in an envelope and sent to the nearest station, would ensure the transmission of their message: thus, that the actual price of a message of fifteen words is rather under twopence-halfpenny. This information was received by many people with pleasure, as they found they could now send their messages at a very economical rate, but others did not accept the information with the same feelings. One gentleman, upon the receipt of the circular, immediately communicated to the company, and remonstrated with them. It appeared that he had a near relation seriously ill, about whom he was very anxious. Upon the receipt of the circular, on the envelope of which was printed "Telegraph Company,"

he was greatly alarmed: so much so, in fact, that he had not been well for several days afterwards, as he of course imagined that his friend must be dead, in consequence of his receiving something from a telegraph-office. It was suggested to this alarmist that the message might have been to announce that his friend was better; but he adhered to the old proverb that only "ill news flies apace," and that the company ought not to have caused him groundless alarm.

This feeling of alarm is very widely spread, in spite of the frequency of domestic messages. For example, a gentleman having met an old friend in London, telegraphed to his faithful spouse to the effect that he should bring this friend home to dinner at six. This simple announcement he believed would be a sufficient hint that something extra should be provided. Alas! there was nothing besides the usual family dinner; the fatted calf had not been slain.

"Why, my dear, did you not receive my telegram, saying that I was going to bring him home to dinner?"

"Thank Heaven, my dear," replied his wife, "my alarm is over. I did receive a dreadful telegraph; but I was so frightened I dared not open it, and there it is on the mantel-piece. I thought you must be killed, or run over, or something, and I've been more dead than alive ever since."

These, and several other similar instances, come almost weekly under the notice of those officially connected with this much-dreaded but very useful power. The district-telegraph is decidedly the most domestic of its class; the fact that it is principally established for the purpose of conveying messages twelve miles round London, enables men of business in town to communicate easily with their families, and their families with them; and should these parties be within a reasonable distance of an office, the cost of the message will be at most sixpence, and if stamps are used, only twopence-halfpenny.

We will now trace the course of a telegraphic message, from its first production at the hands of the sender, to its final delivery to the receiver.

First, we must offer a few remarks upon the selection and omission of words in a message—fifteen words, excluding address, are allowed; and it is of course desirable to convey as much information as is possible in these fifteen words. A person not accustomed to send messages should first write down what he means to say, and then recast his sentence so that he may express the same sense in fewer words. Here, for example, is a message that a friend once sent to us: "Will you meet us to-night at eight o'clock at the chief entrance of the Lyceum; we have front seats in the boxes for four." Here were twenty-five words used to convey an intimation which might have been done in fourteen, for the message, as follows, contains the same sense: "Please meet us at eight, chief entrance Lyceum, we have four front-box seats."

In a telegraph message, a certain amount is left to the common-sense of the receiver—as in the above; no sensible person would go to the Lyceum at 8 A.M. in order to witness a performance; the "to-night" is likewise unnecessary, for unless it had been "to-night," a telegraphic message would have been out of place: and so in many other cases brevity may be adopted with advantage. The writing cannot be too plain and distinct, a school-boy sort of hand being preferable. There are some ever-recurring mistakes in connection with the art of telegraphing, quite independent of mistakes from bad writing, so that it is a sender's interest to make his part of the performance as intelligible as possible.

As soon as a message is written and given to a clerk, the document is read over and placed in front of an instrument. The clerk then "calls" a station, usually that at Cannon-street; and this calling consists of some special movement of the needles, which is always the same for the same station; upon the called station answering, the message is commenced. Each letter composing the words is indicated by a particular series of movements of the needles, which movements are caused by an electric current sent from the first station. This current of electricity is the result of a movement of two handles made at the instrument by the clerk. The current traverses the wire instantaneously; and as it passes through a portion of wire at the other station, it converts this into a powerful temporary magnet, which therefore attracts the needle temporarily, each movement of the handle at the first station causing a movement in the needle of the second. Now, it is by these movements of the needles that the clerks read off the messages; so that the fears of the gentleman who did not wish his handwriting to be recognised by his friend to whom he telegraphed, were groundless, his words being converted into a fluid state, and again reconstructed in the ink-and-paper form at the other end of the wire.

Should the message be from one out-station to another, the clerk at Cannon-street copies the message, and delivers it into the hands of the person who works the particular instrument to which the office for which the message is intended is connected. The clerk there again copies the message, and delivers it to a boy, who carries it to its final destination. A copy of this message is retained at Cannon-street for about three or four months, after which it is destroyed.

The clerks employed at this work are almost all females, there being upwards of one hundred and twenty young girls obtaining a livelihood as telegraph clerks. They receive, on an average, about ten shillings per week; and, as the whole of their time is rarely employed in telegraphing, they are enabled, in addition, to use their own needles, whilst in readiness to read the needles of the telegraph instrument. The hours of work are from 9 o'clock A.M. to 7 o'clock P.M., a tolerably long spell, supposing they were employed all the time in reading the vagaries of the magnetic needle, or in sending messages; but, as intervals of rest are of frequent occurrence, the labour is comparatively light, and of a more attractive kind than mere sewing for a living.

It might be imagined that when messages of all classes are being sent by the aid of a number of young girls, that there was very little chance of a message being private or not divulged, but there are one or two reasons why the public are very sufficiently protected in this respect. In the first place, a telegraph-clerk becomes a kind of automaton; and, in consequence of day after day sending off some half-dozen score of messages, no particular one is likely to impress itself on the memory and be there retained. In addition to this natural cause, it is a part of the service agreement that no clerk divulges the purport of any message; and an act of parliament was passed during last session, rendering any person liable to a penalty of twenty pounds who delayed or divulged a telegraphic message. Thus, in this respect, the public are well protected.

There are now two systems of communicating in almost general use; the first is by the aid of a single needle, the Morse alphabet being in almost universal use. This enables a clerk, independent of his nationality or knowledge of language, to read off the letters from his instruments, so that an English clerk in London might send an English message to Russia, which would be read off by a Russian, and written in English. In like manner, an English girl would be able to read off a message sent in the Russian language, with the same ease that she could one in English. Thus there is a universal language in telegraphing as there is in music.

The other method of communicating is by printing, the various letters being indicated by a series of dots and dashes. From the time of first commencing to study the instrument until proficiency is obtained in reading and sending, two months usually elapse—shorter or longer, according to the talent of the clerk. A clerk is generally able to send a message before she can read one; it is also found much more easy to read the messages sent by one clerk than those by another.

At the present time there are about two hundred and fifty miles of wire, set up on the housetops and underground, for the use of the London and twelve-miles-round telegraph; by the aid of these and the eighty-three stations now open, it would be possible to send about one thousand messages per hour—a quantity sufficient to render the district telegraph a very paying investment. At the present time, however, the number per day, on an average throughout the year, does not exceed one thousand, so that only one-tenth of the work that might be done is actually accomplished.

Some curious statistics are brought to our notice when we examine the causes that influence the number of telegraphic messages. A very fine morning, followed by continued rain from mid-day, is at once a source of business to the telegraph company. Numberless appointments that had been agreed on when the weather was fine have to be put off. Gentlemen who purposed walking home from the station would now prefer their brougham, or their waterproofs, or something to protect them from the weather. The friend who was coming to dine with them will select another day, and this naturally leads to a second message from the disappointed host to his faithful spouse. A very wet morning sometimes causes several extra messages, for the prudent will, at the last moment, sometimes change their raiment in order that they may have nothing on that will spoil, and their keys, unfortunately, are left in those garments

which had been cast off, so that a message is sent to have the keys forwarded by next train.

It is in messages of this kind where the electric telegraph is of immense use, and where any delay at once produces serious inconvenience. It would be of little use to a business-man to have his keys forwarded by a three P.M. train, when he wished for them by one arriving at eleven A.M., and yet, perhaps, half-an-hour's delay on the part of a clerk, or the boy who delivered the message, might produce nearly as great a difference as this on lines where only a few trains run.

When, again, any information has been forgotten, and is required immediately, this district telegraph is very serviceable. On one occasion we went to London, and had an engagement somewhere near Holborn, but the actual address we had left on our dining-room mantel-piece. Telegraphing from London-bridge, we directed the message to be sent to the office at Charing-cross, and we then proceeded by boat to Hungerford. Upon reaching Charing-cross we entered the telegraph-office, and, on inquiring, were presented with the message just arrived, and containing the name of the locality where we were to keep our appointment.

The greatest number of messages ever sent in one day by the London district telegraphs was on the day previous to the Princess of Wales entering London, no less than 1,500 having been received and sent on that occasion; the principal purport of these messages was the engaging of seats and friends, the announcement of disappointments or of expectations—in fact, an endless variety of anxious, eager lines, all with reference to the event of the morrow. On all great public occasions work is brought in to the telegraph, so that the meeting of Parliament, the Derby-day, &c., are days of extra work.

In an upstairs room of the office in Cannon-street there is a kind of cupboard, upon opening the doors of which a mass of wires and screws, bolts and fastenings, are exposed to view; these are all lettered or numbered, and a strange mystery exists with regard to them; they are really the junctions between various station-wires, and thus two extreme stations might at once be placed in connection with each other. We will suppose that B represents the termination of the wires that lead from Blackheath to Cannon-street, by which wires the messages are sent, and C the termination of the Camden-town wires. Now, B and C might be a yard apart in the cupboard, and it would merely be necessary to join these two by means of a wire, in order to allow Camden-town to talk to Blackheath, or *vice versâ*.

A wonderful medley of messages might be read by any curious individual who placed an instrument in any circuit, as it is called, for his needle would move in accordance with the needle at the end of the wire, and thus the message would be read off.

Some singular and amusing mistakes sometimes occur in connection with telegraphing, in consequence of the misreading of a word or letter—the signals for some few words being very similar—that is, the movements of the needles to indicate one word are very like those which indicate another with a very different meaning. A household in the country were rather surprised at receiving a message from the lord and master to the effect that he wanted his wig to be at the London-bridge station by four o'clock P.M. As the gentleman had a very excellent crop of natural hair, of course the family were somewhat perplexed; for "wig" read "wife," and the message was intelligible. A gentleman telegraphs to his friend to the following effect: "I want you to get me this evening at any place you may appoint;" for "get" read "meet." A cautious spouse sent a message to his wife, who received the following: "I am going to bring some hog home for dinner to-night—be ready." The wife, probably expecting a large piece of pork, did not prepare much for dinner, and is consequently very much surprised when her husband returns, and brings with him a very old friend, who is very unlike a "hog." The words "hog" and "one" were unluckily very much alike, and were mistaken the one for the other—"Bring some one home for dinner" was very intelligible.

Considering the number of messages per diem, and the imperfect manner in which addresses are often given, and the badness of the senders' writing, there are remarkably few mistakes.

Occasionally, when the wires are very close together, the rain will bring two wires into contact; then the messages which ought to go in one direction run away with the words, and deliver them in quite another place. Thus, a short time ago some large tea agents were much puzzled by receiving perpetual inquiries about cargoes of beef: "How about the beef?" was an oft-repeated question. Some shipping agents, whose private wires ran down the same line, were equally puzzled at having repeated demands for another chest of unmixed tea. It was very shortly found that the wires had been brought into contact by wind and rain, and thus the message for one firm had flown off at a tangent, and had made its way in a wrong direction.

It is not at all an unusual circumstance to find that certain unscrupulous persons are on the watch to obtain money from telegraph companies, on the plea of losses sustained in consequence of mistakes. Such an attempt was made a short time since. A gentleman having sent a message up to his office in London, saying that he was not well enough to attend business on that day, omitted in his address to say that there were two streets of the same name close together. The boy who had to deliver the message went to the wrong street, and upon looking for the house indicated by the number on the telegraph direction, found that the house was in ruins, and men at work amongst the débris. Having given the information at his office that the house was in ruins, the intimation was forwarded to the sender of the message that, the house being in ruins, the message could not be delivered. Here, then, was a real grievance—a decided case for compensation—for the gentleman, upon hearing the alarming intelligence that his town-house was in ruins, was taken so seriously ill, that it was at first feared he would not recover. A messenger was immediately despatched to London to inquire into the cause of the house being in ruins. Thus, much expense was incurred, and serious loss in consequence of the illness produced by alarm; and therefore the District Telegraph Company ought to fully compensate the gentleman, or he would be compelled, however much against his feelings, &c., &c. But such little matters had been tried on before by other injured individuals, and the gentleman did not receive any pecuniary recompense.

Lightning sometimes produces a temporary stoppage in telegraphing, as the natural electric fluid demagnetises the needles, and therefore renders them temporarily useless. During the severe storm in September, 1863, no less than fifteen stations belonging to the London District Company were rendered temporarily useless by the lightning. In no instance have we ever heard of a clerk being damaged by the electric fluid, although in one case a clerk received a shock. He happened to be standing on a damp floor, and was holding the handles of the instrument very firmly; a storm passing over his circuit gave him a slight shock, which, however, did little more than alarm him.

It is not an uncommon thing to hear of birds being killed by the wires of an electric telegraph, and people unacquainted with the principle of telegraphs not unfrequently imagine that it is the electricity that kills them; this, however, is not the case. If a bird were to become very wet, were then to hold on to the wires with its feet, and stick its beak into the ground, it would then probably receive a slight shock, but birds are not naturally given to practise this experiment. The way by which birds become killed is by flying against the wires by night, and thus striking themselves, become either killed or seriously damaged. So frequently does this occur, that in one large game district a gentleman preferred laying down wires in another place at his own expense, rather than have them going over his land near his preserves.

One of the many advantages derived from our familiarity with the telegraph is the arrangement of all the clocks on railways and in London to Greenwich mean time. When the ball drops at one o'clock at Greenwich, a signal is sent to Cannon-street, and the clock there being thus regulated for Greenwich time, a signal can be sent to all out-stations, or to any private establishments where a knowledge of correct time is of importance.

The majority of our readers have probably heard the singularly melancholy noise that is sometimes made by the wind blowing against the wires that are suspended against the telegraph-posts. It has been asserted by some individuals that when the noise is greatest, rain is sure to fall very shortly; but as the quantity of the noise must in a great measure depend on the direction and strength of the wind, we are bound to deny the accuracy of this assertion as a general rule.

We before mentioned that the majority of persons were not well acquainted with either the principles or practice of telegraphing, and that hence some very amusing mistakes sometimes occurred. We will conclude this article with one, for the accuracy of which we can vouch.

An old lady (this time) had given permission for some wires to be placed on her house, where they were supported by a ... After these had been in position some few weeks, the old lady ...

waited upon the principal telegraph authority, and stated that she had a complaint to make. "The fact is, sir," she said, "them telegraph messages won't allow me to get any sleep of a night; I lays awake, a-tossing about, and can't get a wink for the noise. At first, sir, I didn't mind it as much, and things were not as bad as they are now; but lately, sir, there have been a deal more messages. I don't think either, sir, that you are aware of all that's said along them wires; there's much that hadn't ought to be; for I can assure you, sir, that very much that's said there—and I have to lay and listen to—no respectable woman ought to hear. So I've come at last to complain to you, sir, hoping that it may be stopped."

The gentleman to whom this singular complaint was made was, of course, aware that the noise complained of was the wind in the wires; the messages of a doubtful character were the emanations of a fruitful imagination on the part of the old lady. He, however, pacified her by stating that in future young women of great respectability were to be substituted at the offices for the young men who formerly worked there, after which he received no additional complaints from the wakeful and imaginative old dame.

THE TELEGRAPH IN SPAIN.

WE have much pleasure in laying before our readers two interesting documents connected with the telegraphic establishment of Spain, which have been forwarded to us for publication.

The following important decree has just been issued by the Spanish Government respecting telegraphs and their extension without burden to the State, which we lay before the readers of this Journal, not only to show the views entertained in that country upon this important subject, but to acquaint the different English telegraph companies of matters concerning telegraphy, which cannot fail to be of interest. The young Minister of State for Home Affairs in Spain, His Excellency M. Antonio Cánovas del Castillo (who does honour to the province of his birth, Malaga—truthful example of the Andalusian youth), gives every day practical proofs of administrative capacity, and justifies the high reputation he enjoys, as a jurisconsult and as an economist, by the interest he takes in opening up means of communication, clearly seeing it to be, as it is, the first necessity of the times, and one of the best and most efficacious auxiliaries for the development of commerce,—the foundation of the prosperity of nations.

MINISTRY OF STATE FOR HOME AFFAIRS.

Exposition to Her Majesty.

Madam,—The petitions presented to your Majesty from different towns, various companies, and private individuals are so numerous and repeated, praying your Majesty that the advantages derived from telegraphic communications should be granted to them, that the minister, who now humbly addresses your Majesty has lamented more than once that the care of the government has not extended that satisfaction to legitimate wishes, so deserving of attention, which are so intimately connected with the duties of the administration, in respect to the disposal of the resources at its command, as well as the rights of society, inasmuch as they answer to that end without endangering public interests.

Having respect to the unchangeable principle, that state necessities alone must be borne by treasury funds, and the proper and regulated use of the telegraph being guaranteed, subject to those conditions which now regulate correspondence, not only is the amplitude proposed to be given to this service, free from inconveniences, but must produce most remarkable and advantageous results, as is clearly indicated by the repeated and general applications from localities as yet deprived of its benefits.

To answer to this wish in a satisfactory manner, the minister, who now humbly addresses your Majesty, thinks that it will only be required to bear in mind two equitable conditions,—First, that the services of local and private interest should be defrayed by those who require and profit by them; and, second, that bound up as they must be with the general working, they cannot in any way cause the least interruption in this, neither by its material conditions, nor in the tenor of the correspondence. These two indispensable conditions being adopted, as they are by the annexed project, there does not appear the least danger or difficulty in granting this concession, for an unlimited extension to the telegraphic lines, so much desired by towns, companies, and even by private individuals, a measure imperatively demanded by the necessities and requirements of daily occurrence, which constitute the only rule to fix the extension and nature of the new service; and this will be realized, at the same time diminishing the burden imposed at present upon the treasury by this important branch, placing it upon a better footing to fulfil its mission, thanks to the increase of lines, without imposing on districts or private individuals more expenses than those incurred in working them, and accepted with previous knowledge and free will; all this to be under equitable regulations, which will not admit of question.

If this suggestion should merit your Majesty's good pleasure, would your Majesty deign to sanction the annexed proposed decree.

(Signed) ANTONIO CANOVAS DEL CASTILLO.

Madrid, March 30, 1864.

ROYAL DECREE.

In conformity with what the Minister of State for Home Affairs has proposed to me, upon organising the concession of lines and telegraphic stations,

I have decreed as follows:—

Art. 1. The districts, towns, companies, and public establishments who wish to form new lines or stations, can solicit them from the government, pointing out the daily working hours which they desire. The government will enquire into the influence of the establishment of the said lines or stations upon the state telegraphic system, and will fix the point or points at which it must be joined with the provincial, municipal, or private service, its cost of installation, and the continuous expenses of staff and material, in all respects which that service may occasion, either directly or indirectly by its influence on the general organization.

Art 2. The necessary cost of installation and service of the lines or stations will be communicated to the petitioners when ascertained by the government, and the petitioner will have to declare if he is prepared to pay the amount to the state. In case he should be ready, the government will fix the scientific staff for the establishment, which will be carried out, either by the administration, or by the parties interested in it, at their choice and expense; and they will have also to give sufficient guarantee for cost of repairs and service; and if the petitioners represent a province or a town, they will have to be inserted in the provincial or municipal budget as obligatory. If the interested parties should undertake to form the plan, it will be carried out in accordance with the fixed rules for telegraphic lines established by contract.

Art. 3. The petitioner will be obliged to pay to the state the difference that may result between the annual income from the correspondence carried through the stations granted, and the cost of the service, and keeping up the same; also that of the reforms demanded by the necessity of the case in stations or lines previously established. The official correspondence will be reckoned as private, and its amount will be credited to the stations to which it corresponds.

Art. 4. If at the expiration of five years the expenses exceed the returns, the line or station, wherein so happens, will be considered as property of the state, and the government will proceed with the reimbursement of the expenses to the locality which has had the line. This is not applicable to the case of companies or establishments, public or private, which have given guarantees of permanent profits.

Art. 5. No line or station can be formed in future without being previously taken in consideration by the ministers in council as to its official convenience, or through a petition based upon the conditions laid down in this decree.

Art. 6. It is understood that the service in all kinds of stations and lines cannot be performed, according to law, by others than by a staff from the telegraph body.

Given at the Palace, on the 30th day of March, 1864.

I THE QUEEN.

The Minister of State for Home Affairs,
Antonio Cánovas del Castillo.

THE ELECTRIC LIGHT—It does not appear to be generally known that lighthouse illumination, produced by a magneto-electric apparatus, has been in successful operation at the South Foreland and Dungeness beacon, for two years. Currents of air, produced by the rotation of masses of iron in the neighbourhood of powerful permanent magnets, generate the current of electricity, which ignites pieces of carbon intensely, thus producing the light.

THE INTERNATIONAL EXHIBITION, 1862.

(Continued from page 209.)

3. *Galvanometers.*

Siemens, Halske, & Co., M. (United Kingdom, 2,959), exhibit several forms of galvanometer.

1. An instrument which can be used both as a *sine* and *tangent galvanometer*, with extra coils or shunts of various resistances, each being a known fraction of the resistance of the galvanometer coils, and designed to be connected with those coils in multiple arc, so as to divert various fractions of the current, and reduce the sensibility of the instrument as may be required. The analogy, in virtue of which these auxiliary coils are called shunts, is sufficiently obvious.

2. A Gaugain's tangent galvanometer—that is to say, a tangent galvanometer, the coils of which form part of the surface of an obtuse cone, the apex of which corresponds with the centre of the suspended magnet. The angle at the apex of the cone is such that the height of the cone is equal to one-fourth of the diameter of the base. In this instrument the readings can be very conveniently taken, and the tangents of the deflections are said to be more truly proportional to the strengths of the current than in the old form.

In order that these tangents and currents should be strictly proportional, it is necessary, in the old form of the instrument, to suppose the suspended magnet to be infinitely short in comparison with the diameter of the deflecting coil; and if the true length were as great as one-sixth of that diameter, the want of strict proportionality might introduce an error of 30 per cent.; whereas, under the same circumstances, the error with M. Gaugain's instrument would not exceed $\frac{1}{3}$ per cent.* This instrument is also exhibited by Messrs. Digney Brothers, of Paris.

3. A very delicate astatic sine galvanometer, used for testing short lengths of submarine cable by measuring the deflections produced by the current from a given battery passing from the inside to the outside of the insulated wire. Indirectly, as already mentioned, the resistance of the sheath can be calculated from these deflections. This instrument is also used in connection with Messrs. Siemens' testing board previously described. The copper wire used for the deflecting coils makes 22,752 turns round the needle, and its resistance is 7,000 of Siemens' mercury units. The astatic system is suspended by a single fibre of floss silk, and the instrument is provided with a reading telescope, to avoid parallax in observing the position of the needle. It is similar in general arrangement to the galvanometers used by Ruhmkorff and Dubois-Reymond.

4. A marine galvanometer. This instrument is intended for use at sea in connection with the testing board. It consists of an astatic system, each magnet of which is surrounded by a deflecting coil. These magnets are supported on a vertical axis working on pivots. A strong adjustable directing magnet is fixed above the coils. This instrument is used in connection with the electric balance, to show simply the presence or absence of a current when the battery circuit is completed, as explained above. The deflections afford no *measure* of the deflecting currents.

Elliott Brothers, M. (United Kingdom, 2,897), show a convenient and cheap form of the common astatic galvanometer. This firm has taken especial care to provide diamagnetic copper for the coils: a point of importance in the very delicate differential instruments which they supply.

French makers show several excellent instruments of the usual forms.

J. White, Glasgow, M. (United Kingdom, 3,012), exhibits Professor W. Thomson's marine galvanometer. This instrument, designed and used for the tests of the Atlantic cable, allows every galvanometric measurement which can be made on land to be repeated at sea.

The suspended magnet is extremely small and light, and is fixed to the back of a little circular glass mirror, which, together with the magnet, weighs about $1\frac{1}{2}$ grain. The magnet and mirror are strung on a vertical bundle of stretched silk fibres passing through the centre of gravity of the magnet mirror, and secured both at top and bottom to a thin brass ring about $2\frac{1}{4}$ inches in diameter; on either side of this ring, and closely surrounding the mirror and magnet, are placed the two circular deflecting coils, having a small cylindrical opening in their centre of a diameter a little larger than that of the circular mirror. In this opening two stops limiting the deflections are placed behind the mirror, and a lens in front of it. A lamp placed in a frame with the magnet and coils at about two feet distance throws its light through this lens on to the mirror, which reflects the rays back through the lens, and this concentrates them into an image of the flame on a horizontal scale a little in front of and over the lamp. The reflected image traverses to and fro on the scale as the magnet and mirror are deflected to the right or left.

As the mirror and magnet are supported by their centre of gravity, the supporting frame may be moved in any direction without producing any change by the action of *gravitation* in the relative position of the mirror and its support; or, in other words, without altering the relative position of the frame, and the image on the scale. The effect of the *earth's magnetism* is equally neutralized by a very powerful horseshoe magnet fixed on the frame outside the coils. The directing force of this magnet on the suspended magnet is infinite compared with that of the earth. Thus, in spite of gravitation and of the earth's magnetism, this instrument may be moved into any position without altering the position of the little suspended magnet relatively to the frame, and consequently without altering the position of the reflected image on the scale. On the other hand, the passage of any current through the coils will always deflect the suspended magnet, and equal currents will have equal effects, whatever be the position of the instrument, so long as the directing horseshoe magnet remains constant; moreover, owing to the very small angular deflection which suffices to cause the spot to traverse the entire scale, the deflections of this spot may be taken as strictly proportional to the deflecting current. The image or spot may be adjusted to zero (which is in the centre of the scale) by moving the directing magnet with a screw adjustment provided for the purpose.

Galvanometric observations of all kinds can be easily made with this instrument in the roughest weather at sea; neither the continual alteration of the ship's course, nor the motion due to the waves, has any effect on the deflections. The instrument can be made either with differential coils, or with simple coils to be used in connection with a Wheatstone's balance, or it will indicate the loss by direct deflections. It may also be used as a receiving instrument for messages, since the movements of the spot of light can be as readily interpreted as those of any single needle receiver.

A jar will not derange the instrument, and there are no metal bearings which can rust; its practical value is now well known, and has been tested by several years' experience in the hands of various electricians. It cannot, of course, be made as sensitive as galvanometers with needles suspended by a single thread, and directed by the earth's magnetism, or, indeed, by a fraction of that magnetism; both the method of suspension and the power of the directing magnet reduce the magnitude of the deflections with any given current, but the action on the little magnet from the coils which so closely surround it is amply sufficient to render the instrument sensitive enough for all practical purposes when considerable lengths of cable are to be tested.

For very sensitive instruments to be used on land, the same general arrangement may be adopted without the directing magnet, and with the usual single thread suspension, instead of the stretched bundle described.

The messages which were for some time received through the Atlantic cable from America were translated from a somewhat similar instrument, by what Professor Thomson calls a human relay. A clerk worked the local circuit of a common Bain's receiver with a Morse key, by depressing and raising the handle as the spot of light moved in the one or other direction along the scale.

4. *Electrometers.*

James White, Glasgow (United Kingdom, 3,012), exhibits an electrometer, constructed by him according to the design of Professor W. Thomson, of Glasgow. The function of this instrument is to measure the difference of potentials between the earth and any given insulated body. The index of the instrument consists of an aluminium needle strung on a fine platinum wire passing through its centre of gravity, and stretched firmly between two points. The needle and wire are carefully insulated from the greater part of the instrument, but are in metallic communication with two small plates fixed beside the two ends of the needle, and to be called the needle plates or repelling plates. When uninfluenced by any electrical force the needle stands in a sighted position, which will be called zero, and it can always be brought back to zero by a torsion head turning one end of the platinum wire, but insulated from it. This torsion head is provided with a graduated circle, and the number of degrees of torsion required to bring the needle to zero measures the force tending to deflect it, as in a Coulomb's balance.

* Professor Thomson informs the writer that M. Gaugain's arrangement is apt to introduce an error of a distinct nature, and more serious than that corrected by it.

The needle and its repelling plates, considered separately from the rest of the instrument, would form a Delmann electrometer, with the variation of having the needle suspended by a metallic wire, and so kept in connection with the repelling plates, instead of being suspended by a glass fibre, and only temporarily connected with the repelling plates in the course of an experiment; whether positively or negatively electrified, the plates would repel the needle. This action is much modified by the presence of a second pair of larger plates facing the first-mentioned plates on the opposite side of the needle, and considerably further from it. These plates are in connection with the inner coating of a Leyden jar, which is intended to be permanently charged to a high potential either negative or positive, and they will be called the Leyden jar plates, or the attracting plates.

The whole instrument is enclosed in a metal cage to protect the glass of the Leyden jar from injury. The inner tinfoil coating of the Leyden jar, and a wire cage in connection with it surrounding the needle, protect it from the irregular electric action of surrounding objects. The action of the instrument is as follows: The Leyden jar and its plates are to be charged to a high potential—say negatively. Let the needle and its repelling plates be connected with earth, or, in other words, be maintained at the potential zero. The needle will then be deflected against a stop, under the combined influence of attraction from the Leyden jar or attracting plates, and repulsion from the small or repelling plates, due to the positive charge induced on the small plates and needle by the Leyden jar plates. The platinum wire must then be turned round by the torsion head so as to bring back the needle to zero, and the number of degrees of torsion required will measure the force with which the needle is attracted. The square root of the number of degrees observed is proportional to the difference of potentials between the earth and the inner coating of the Leyden jar, and will, therefore, measure this potential in a certain arbitrary unit depending on the size and position of the needle and plates, and on the stiffness of the platinum wire to resist torsion. This observation is called the earth reading.

Now let the needle and its plates be disconnected from the earth, and connected with the insulated body, the potential of which is to be tested. If the potential of this body be positive, the charge induced by the Leyden-jar plates in the small plates and needle will be greater than before. The needle will consequently be more attracted by the large plates, and more repelled by the small plates; if, on the contrary, the potential of the body be negative, the Leyden-jar plates will induce a smaller charge on the small plates and needle, which will consequently be less attracted by the large plates, and less repelled by the small plates: the needle will therefore be deflected to one or the other side, according to the sign of the potential of the body tested. The platinum wire must again be turned till the needle is brought to zero, and the number of degrees observed. The difference of potential between the Leyden-jar plates and the needle is in this case, as well as in the last, proportional to the square root of the number of degrees observed, and this new square root measures this new difference of potential in the same arbitrary units as are above alluded to. Thus the two square roots of what may be called the earth and test readings measure the two differences of potential of the earth and conductor tested, from one and the same Leyden-jar plate, in one and the same unit, and so the difference between the square roots will measure in the same units the difference between the differences, or what comes to the same thing, the difference between the potentials of the earth and of the tested conductor.

To express this mathematically, let a be the number of degrees observed for the earth reading, and b the number of degrees observed for the test reading; also let the potentials of the Leyden-jar plates, the earth, and the tested conductor be called L, E, and T respectively. Then we have

$$E - L = \sqrt{a}$$
$$\text{also } T - L = \sqrt{b}$$
$$\text{therefore } T - E = \sqrt{b} - \sqrt{a}$$

that is, the difference of potential between the earth and the body observed will be measured by the difference of the square roots of the degrees of torsion observed. The units in which this measurement is expressed will be unaffected by any change in the potential of the Leyden-jar plates—a most important and, indeed, essential feature of the system; for whatever be the value of L in the above equations, it is eliminated from the final result. It is only essential that during the two observations of a and b, the potential L should remain constant, a condition which is easily fulfilled during some hours with the present instrument. The sensibility of the instrument varies, however, with the potential of the Leyden-jar plates, increasing as this increases; for the required measurement is equal to the difference of two numbers, large when L is large, and small when L is small; and although this difference is constant, the difference of the squares of these numbers, which are the readings actually taken, will be by no means constant, but will increase as the numbers themselves increase; thus, let $T - E = 3$, and $E = 0$,

$$\begin{aligned} &\text{then if } L = -1, & E - L &= 1 = \sqrt{a}, &\text{and } a &= 1, \\ && T - L &= 4 = \sqrt{b}, &\text{,, } b &= 16; \\ &\text{but if } L = -10, & E - L &= 10 = \sqrt{a}, &\text{,, } a &= 100; \\ && T - L &= 13 = \sqrt{b}, &\text{,, } b &= 169; \end{aligned}$$

so that in the first case the difference between the a and b which measures the sensitiveness of the instruments is 15, and in the second case 69; or, in other words, the instrument was, by charging the Leyden-jar plate to a potential 10, made more than four times as sensitive as when the Leyden jar was charged to only 1.

A single comparison of a measurement of $T - E$ so obtained with the measurement of the difference of potentials by an absolute electrometer, gives a co-efficient by which this, and all other measurements, can be reduced to absolute measure. (By absolute electrometer is meant an instrument which measures the difference of potentials in electro-statical absolute units depending on time, mass, and space only.) Any loss of charge from the Leyden jar which may from time to time occur, reducing the sensibility inconveniently, may be made good by additions from a small electrophorus which accompanies the instrument.

Measurements could be obtained if the needle-plates were quite removed, but the deflections would be diminished, and what is of more consequence, a reading taken with the needle deviating very slightly from the true zero position would entail a great error in the measurement recorded. In other words, one object of the needle-plate is to give sensibility to the zero position of the needle by causing a great alteration in the force experienced by it, when deviating a little to the right or left of this position. If the Leyden-jar plates, instead of being permanently charged, were simply connected with the earth, deflections would still be obtained when the needle is charged, and the sensibility of the instrument would even thus be somewhat greater than that of a Delmann electrometer, in virtue of the attracting or Leyden-jar plates; but no distinction would be shown between positive and negative electricity. The effect of charging the Leyden jar is twofold: it increases greatly the sensibility of the instrument, and allows us to distinguish between positive and negative electrification.

The atmosphere inside the jar is maintained in an exceedingly dry state by pumice-stone slightly moistened with sulphuric acid, and thus the very perfect insulation required is obtained. The insulation of the jar is such that it will lose a charge only at the rate of about 1 per cent. per diem when in very good condition, and 5 per cent. per diem when in indifferent condition. One earth reading therefore suffices for comparison with a series of test readings (made for example in a balloon), occupying several hours. Electrodes or terminals are brought outside the instrument, by which the Leyden jar can be charged, and the needle system connected with the body to be tested. The needle is so accurately suspended by the centre of gravity, that the deflections are independent of the instrument, and observations can be made on it when held in the hand, and even when in motion. Along with the instrument are exhibited arrangements for testing the potential of the atmosphere. This is done by means of a burning match in connection with the needle system when the instrument is moved from place to place, and by a water-dropping collector when stationary.

Mr. White, the exhibitor and maker of this instrument, has shown great skill in the successful execution of the difficult details of Professor Thomson's novel and ingenious contrivance, a more complete description of which will be found in a paper read before the Royal Institution by Professor W. Thomson on May 18, 1860, and also in an article on atmospheric electricity in the second edition of Nichol's "Cyclopœdia of the Physical Sciences."

Elliott Brothers (United Kingdom, 2,897) exhibit a convenient form of Peltier's electrometer, in which the needle and repelling plates are insulated by a composition of gum damar and Venetian turpentine. These instruments retain a nearly constant charge for some time unaided by an artificially dried atmosphere. At the end of twenty-four hours the deflection due to the charge will frequently be found not to have fallen more than one-half.

ON THE PATENT LAWS.

In our last we published a very important paper, on the above subject, from the pen of Thomas Webster, Esq., M.A., F.R.S., which was read at a recent meeting of the Society of Arts; we now lay before our readers a report of the interesting discussion that followed, in the course of which some novel ideas were ennunciated by the various speakers.

Discussion.

Mr. Robert Wilson would say a few words on the improvement of the existing patent laws, rather than go into the more abstract question whether those laws were expedient in themselves. For his own part he could not see how they could expect to maintain invention if they deprived it of its reward. In his opinion the first question to be considered was whether they could amend the existing laws: and he thought it possible to do so in many important respects. One great improvement would be to enforce precision in the specification of the invention. It was a condition in every patent that the patentee should, within six months, file a specification describing his invention, and the manner in which it was to be carried into effect. But how was this complied with? In a large number of cases at the present day patents were taken out, not for things entirely new, but for modifications of existing inventions, and in such cases he submitted the description might clearly distinguish what was new from that which was old. But those who were conversant with the subject knew that such was not the case, for it constantly happened that patentees put in descriptions which did not distinguish clearly the new from the old, but left it to the public to pick it out for themselves, instead of saying "the old machine is defective in certain points, and I have introduced a certain improvement," and then described the whole machine, pointing out distinctly the improvement which he sought to introduce and make the subject of his patent. Patentees, however, generally began with an obscure description of the machine as a whole, and then referred to the alteration or modification proposed to be introduced; they so worded this description as to cover any possible combination or arrangement in which this might be carried out. They then waited to see what other people where doing. After a time they attacked some man for infringement, and endeavoured to show that what he was doing was covered by the words of the specification; an action was then brought, able counsel engaged to describe the combination, beautiful models were prepared to exhibit these combinations, an array of witnesses were called to say that such a combination was found in the specification. Such a state of things was most injurious and dishonest, and this could be remedied by compelling every patentee to describe distinctly and clearly the exact nature of his invention. Again, it frequently happened that much colateral and irrelevant matter got into the case—the case went to a hearing before a jury, and the heads of the jury, and even the judge, were so full of the plaintiff's good deeds, as detailed by his counsel, and the defendant's iniquity, that it was next to impossible to divest them of that prejudice. The case went on, perhaps for weeks, and in the end the jury found for the plaintiff. The defendant, no doubt, could and did apply for a new trial, which might or might not be granted, and if it was a case of great importance an appeal might be made to the House of Lords, and after two or three years' litigation it might be, and frequently was, discovered that the thing which had been the subject of the contest was not in the specification at all, and had not been claimed as the subject of the patent. In the end it was found that the patent was bad, and the defendant gained the day, but at a heavy expense, a portion only of which he could recover from the plaintiff, and this only if the latter was capable of paying it. Such, he believed, was not an over-coloured history of a great many patents. What was the remedy for this? It seemed to him that it should be the duty of the judge, in the first instance, to see what was in the specification, and what the patentee claimed for his invention. If the patentee had not stated this so distinctly that people could understand what the invention clearly was, and how it was to be affected, the plaintiff should be nonsuited, and the defendant should not be called upon to defend himself. He would give a case in illustration of this. It was well known that litigation had been going on for a long time relative to the patent rights of a certain sewing-machine. A gentleman, of whom he desired to speak with all respect, had purchased the patent rights in a certain sewing-machine in America for £50, and this of course he had a right to do, and, if the patent were good, to have the benefit of it. An action was brought against his (Mr. Wilson's) client for infringement, and the plaintiff was nonsuited. He then brought an action against the same party before another judge, and at the end of six days the special jury, not being able to agree upon a verdict, were discharged. The same plaintiff then brought another action, which lasted three or four days; and at the end of that time the defendant, though advised that the patent was bad, was induced to submit to a verdict on certain terms. The plaintiff having so far succeeded, then attacked every one who he considered was infringing his patent, and filed a separate bill in Chancery against them, somewhere about 130 separate Chancery suits. An application was made to one of the Vice-Chancellors to consolidate this litigation, and to decide the case in one trial; but this was refused, and if it had not been for the Lord Chancellor, who would not allow such a scandal to be perpetrated, there would probably at this time have been 130 suits in Chancery going on on this matter. The Lord Chancellor, however, insisted upon having the whole thing tried in one suit before him, and at once called attention to the specification, sitting day after day in order to give the plaintiff's counsel full opportunity of showing that what was relied upon was covered by the specification. It turned out, however, that the invention claimed was nowhere to be found in the specification at all, and the Chancellor upset the patent. These facts went to show the necessity for explicit description. There was, however, another matter to which he desired to draw attention. When the defendant in a patent case put in his pleas he was bound to deliver a statement of his objections to the validity of the patent. Those objections generally consisted in the recital of a mass of specifications of a number of other patents alleged to have anticipated the invention in question, and counsel had to sift from this mass of matter what was really of value to the case, whereas the defendant should be required to point out and define what particular parts of these specifications he relied on for his objections. There was another point to which he would refer, and this affected the principles on which a patent was granted. At present a patent was granted for any new manufacture. If a man took out a patent for a machine that would not work, or for a candle that would not burn, the patent was void, because they were not manufactures at all; but suppose a man took out a patent for a machine which would work, or for a candle which would produce light, he apprehended the patent was in itself good, though the machine might be less effective, or the candle less brilliant, but at the same time more costly, than those formerly in use. In other words, the patent law required absolute and not relative usefulness. He could not conceive on what principle a man should have the right of shutting out other people for three, seven, or fourteen years, unless the invention conferred some benefit upon the nation by publishing it. Therefore, he contended, a change was required in the principle of the patent laws from novelty to actual merit. He thought it would be found it was not impossible to work this out. Suppose they had first of all the application for the patent as it was at present: the patent would date from that time. Then suppose the specification was filed: then the third stage would be the sealing of the patent. At this stage the specification would have been printed in detail, and the patentee should then make a formal application for the sealing of the patent, and this might come on to be heard in public before the new Patent Court, or some such tribunal, and the patent could be sealed or not after hearing all that could be urged in favour or against it, and thus an immense amount of rubbish would be got rid of, and people would be more careful in applying for useless and obstructive patents. This plan would effect what had been suggested in the paper, viz., a preliminary investigation, the only difference being it would be done publicly instead of privately, avoiding proceedings liable to much abuse. At the same time he would reserve the right of appeal to another court, although under such circumstances he thought the appeals would not be very frequent. Such a proceeding would be very analogous to the applications made to the Privy Council for a prolongation of the term of a patent. It had been objected to this course that a poor inventor would thus be led into litigation before he could have made anything by his patent. The answer to that was that there was no reason why it should cost the plaintiff anything. He might go before the lower tribunal, or even the Privy Council, and describe his patent himself, then there would be no cost. Then it might be said that a proceeding of that kind would shut out many good patents and let in many bad ones. It might be said such inventions as gas and the screw propeller would never have passed through such a preliminary investigation. The answer to that was, that when an invention was laid before a body of scientific and competent men it was not likely to be pooh-poohed, if it was a valuable invention. Besides that, the necessity for merit would be less in the case of an invention of that kind than in the case of an invention which dealt with an existing manufacture. If a man now applied for a patent affecting an existing trade, it should be shown that the invention was a good one: but if it did not interfere with others, as in the case of the screw propeller, it might pass with much less belief in its merits on the part of the court of investigation than in the other case, or the hearing might even be postponed, and the patentee might come again. He thought it was impossible to defend the patent laws as they existed, and the system was getting worse. They must either improve this system, which he thought might be done, or make up their minds to give up the patent laws altogether.

Dr. Collyer thought the subject of patents admitted of easy and simple elucidation. Men who had money did not, as a rule, devote themselves to invention. To be an inventor necessitated a prior education and intelligence. There were exceptional cases; but almost all the great inventions had been accomplished and perfected stage by stage, and year by year; and those who were most conversant with inventions and inventors, knew very well that invention begat invention, and in the majority of cases it required a large expenditure of money to put them into practical execution. Defects had to be remedied, and it was only after many years that an invention was perfected. At the same time there had been valuable inventions, no doubt, which had not gone through those stages. The steam-engine of Watt had to pass through all these stages, and even now improvements in the steam-engine were daily going on; and were it not for the protection which the patent laws afforded, very few men would devote their time and intelligence to invention. Many men were called inventors who had no right to that title. A host of patents existed which

were the cause of the objections raised so constantly against the patent laws. This would be met, as suggested in Mr. Webster's paper, by a preliminary examination. That plan had been very successfully carried out in America. With regard to the value of an invention to the authors, that could not be anticipated. The value of it could only be determined by the working, after a sufficient time had elapsed. He had himself taken out no fewer than fifteen patents on one subject, and he believed he had now arrived at something like perfection. He would like to see the patent laws revised. They all felt the difficulties that had been pointed out by Mr. Webster, but he would say, as an inventor, he hoped that these difficulties would not deter them from endeavouring to amend the system, and retain the patent laws, to abolish which would be to rob a man of the fruits of his intelligence, honest perseverance, and industry, and be a disgrace to the advancement of civilization.

Dr. BACHHOFFNER, as the proprietor of several patents, had no hesitation in stating that the present law was a delusion and a snare. But, though much might be said against the system itself, much more might be said against inventors. The gentleman who first addressed them had given a graphic description of the intricacies of the law. One of the most ticklish things of all was the provisional specification, and next the final specification. He would appeal to Dr. Collyer whether the object of the inventor was not to disguise as much as possible what was intended to be done, and to tell the public as little as possible for fear of infringement. A man might invent, or fancy he had invented, something that had not been invented before, and the difficulty was to know whether any one had invented such a thing previously. A cautious patent agent would advise him in his specification not to claim anything specific, but to leave it open to his opponents, if he had any, to find out what he did claim. That was the state of patent specifications generally in this country. He fully concurred in the view taken by Mr. Webster as a fair and proper one, but there were great difficulties connected with it. It had been suggested that there should be a judicial council to investigate the claims to patents; but in the case of a chemical patent, how could a fair decision be arrived at when the process dealt with was an entirely new treatment or combination of chemical elements? If the patent were granted, it must be on the *ipse dixit* of the applicant, and rights would thus be created with possible injustice to others, because a patent when thus granted, to be of any value at all, must be one that could not be overturned. As the law of patents now stood, when an inventor had paid the money for the patent, all he got was the privilege to go to law to defend it. The subject was one which it well became this Society to grapple with—how he scarcely felt competent to suggest—but it was important that something should be done to wipe away this great disgrace from the laws of the country.

Mr. PAUL remarked that before they could consider how invention was to be encouraged and inventors rewarded, it was necessary to define what was an invention. No doubt many of the patents granted were not valid, and the majority of them were neither novel nor useful. Mr. Webster, in his paper, had pointed out what he considered a distinction between discovery and invention. He must say he could not altogether realise the distinction which had been thus drawn, and he regarded many patented inventions as essentially discoveries. It was difficult to assign to each particular individual the degree of credit that belonged to him, and that remark applied to almost all the subjects for which patents could be obtained. As the knowledge of scientific principles became enlarged the area of novel invention became more and more narrowed. That was particularly the case in the matter of chemical patents. It was almost impossible to say with regard to chemical patents where the novelty of the invention was, what particular portion of it that was essential to the process was new, and what portion though essential was old. It occurred to him that it might be of great advantage if the character of novelty in these matters were somewhat less strictly insisted upon or limited, so as to admit of retrospective application. In the distinctions drawn by Mr. Webster between discovery and invention, vaccination had been adduced as an illustration of the argument. The novelty as well as the utility of that practice had been established, but yet vaccination was stated to be incapable of reward as an invention; at the same time patents were granted for medicines that were to cure all imaginable diseases. There appeared to him an inconsistency in this. With regard to the reward to inventors and the property in inventions, the inventor was not always the person rewarded by the operation of the Patent Law.

Lord ALFRED CHURCHILL, M.P., said that the patent law of this country was in a most unsatisfactory condition, and that amendments in it should be made was almost universally admitted. The great difficulty was to discover the direction in which the amendment should take place. They could not disguise the fact that in the opinion of many persons it would be best that the patent law should cease altogether, but he for one could not admit that, until some other means were adopted for giving a fair reward to inventors for what they produced. The proposition he thought deserving most attention was the third which had been submitted by Mr. Webster in his paper, viz., that the owners of a patent should be compelled to grant licenses, or to sell the whole right, for the benefit of the public, on adequate consideration. Now the very same idea occurred to him, and he had embodied that principle in a skeleton bill, which he had submitted to the consideration of his friends. The object of that bill was that a patentee should not possess an exclusive or obstructive monopoly in the use or manufacture of his invention, but that he should have full claim to a royalty from other persons for making use of his invention. He proposed in this skeleton bill, first, that no monopoly clause should be introduced; secondly, that parties obtaining patents should declare what royalty they considered would be a fair remuneration to them; thirdly, that the amount so declared should be advertised in the most public manner; and fourthly, that at the end of six months or any other fixed period the public generally or any manufacturer should have power to object to that royalty, and that then the amount should be decided by arbitration. He thought if these points were well considered they would find that inventors would obtain ample remuneration. He could imagine no greater misfortune to a man without means than to be an inventor. He knew of thousands of cases in which men had been ruined by their own brains. If they could have the means of placing their inventions before the public in some such way as he had pointed out, with a certainty that they would obtain a royalty proportionate to the value of the invention, they would not be induced to follow the course mentioned by Dr. Bachhoffner, of drawing out their specification in such a way that nobody could know the meaning of it. On the contrary, they would be anxious to state the nature of the invention as clearly and fully as possible, in order to obtain the royalty which attached to it. He was glad to find that this idea had been entertained by Mr. Webster, and he had no doubt that gentleman, with his large knowledge of the subject, would be able to apply it in a practical and useful manner.

Mr. PETER GRAHAM said he would offer one or two observations on the general policy of granting patents. The broad principle to be considered was this, viz.—whether the granting of patents conduced to the progress and improvement—and thereby to the benefit—of the public? It had been lost sight of so far, that something more than mere invention was required —it had to be brought into practical use. An invention was often attended with many trials and difficulties, and in some cases thousands of pounds were expended before any practical results were arrived at. Men would not be foolish enough to waste time and risk capital unless there were some chance of ultimate advantage from it. Hence, he contended that the principle of the patent law was just, and tended to progressive improvement and public benefit. With regard to the application for extension of the term of patents, he thought this was necessary; when a man brought forward a new invention, affecting an established manufacture or trade, he had all prejudices to contend with before he could bring it into use, and unless he was in a position to carry it out himself, he must find persons willing to bring it forward, and great sacrifices were frequently necessary to this end. He recollected when the power-loom was first adapted to the manufacture of Brussels carpets. The inventor, in the first instance, took it to Kidderminster, the great seat of that manufacture. The answer given by the manufacturers was, first, that they did not believe that it was practicable, and secondly, if practicable, they did not desire any change or improvement in the carpet manufacture. In another instance, in which an ingenious man invented a new thing in connection with the same branch of manufacture, it was agreed to put the thing to work, but the parties afterwards paid the forfeit of £200, and gave it up. However, the invention was subsequently applied by the inventor himself, and it had been the foundation of one of the most colossal manufactures in this country. Would any one tell him that the inventor would have spent his time and money in that way if his invention had not been protected by a patent, and if he had not had anticipations of reaping the reward of his invention? With regard to the means of obtaining patents, he thought that at present they were obtained with too great facility. The suggestion of Mr. Webster, with reference to that point, was a good one; but with regard to Mr. Wilson's proposition, he did not think it practicable, for a poor man would not have the time and money to do it, and, as had been remarked by a previous speaker, rich men were not generally inventors. They found capital to perfect the inventions of others, but they were not the real inventors. They had large manufactories or warehouses, and they were, in many cases, content to continue as they were, and did not encourage inventors to come amongst them. No doubt thousands of patents were perfectly useless, and in like manner there were a great many laws on the statute books which might be abrogated with benefit to the community. He thought the suggestions of Mr. Webster for the improvement of the patent laws were valuable. He thought the public, and particularly the Society, were indebted to that gentlemen for the manner in which he had brought this subject forward. He agreed with every principle laid down, and with every opinion expressed in the paper, having for the last twenty years had much to do with many patents.

(To be continued.)

THE INDIAN TELEGRAPH.—The following telegram was received at the India Office on the 2nd inst.:—"Colonel Stewart requests me to inform Sir Charles Wood that the cable was landed at Fas on the 29th March, and its junction with the Turkish line was effected on the 8th of April. The telegraphic line between Irak and India is now completed, and works nicely. Communication between Bussorah and Kurrachee takes place in five minutes. Two English steamers ply on the Tigris; a third one expected from Kurrachee, to convey correspondence till completion of the Irak line (Persian line); will be completed in July."

DABOLL'S FOG SIGNAL.

(*Continued from page* 210.)

We trust that the reproduction in our columns of this interesting Report, will incite some of our readers to invent a code by which the trumpet, bell, and gun, can be made the means of communicating between the shore and the vessels at sea, so as to warn them of the danger of their position.

REPORT OF A COMMITTEE OF THE ELDER BRETHREN, WHO PROCEEDED TO DUNGENESS TO TEST VARIOUS FOG SIGNALS.

Mr. Daboll's fog-horn having been so fully reported on by the last committee, it would be needless repeating the same, but the machine was in the same position as before, and attended to by a skilled engineer.

An 18-pounder gun had been placed on a platform placed in line with the fog-horn, 100 feet to the eastward of it, manned by some of the Coast Guard.

Mr. Holmes' steam whistle was unable to be used, the steam pipe having burst from the frost.

The following programme of experiments was arranged and carried out, the day, peculiarly adapted for the purpose, being fine, with light variable airs, and calm and smooth water :—

Fog-Signal Experiments, on Friday, 8th January, 1864.

The experiments to commence at 1 p.m., in the following order :—

	H. M.	H. M.	H. M.	H. M.	H. M.
1. Daboll's horn, for 3 minutes	1 0	1 12	1 24	1 36	1 48
2. Gun	1 3	1 15	1 27	1 39	1 51
3. The bell, for 3 minutes	1 6	1 18	1 30	1 42	1 54
All together, 2 minutes continuously	1 9	1 21	1 33	1 45	1 57

Recurrence of the Series as in the Table :

To be observed in three directions right off the point, and in a line in a S.W. and N.E. direction at half a mile, 1, 2, 3, and 4 miles.

Another series of sounds, beginning at half-past two o'clock :

Altogether for 2 minutes.—Silence for 2 minutes.

Altogether for 2 minutes.—Silence for 2 minutes.

Observed at different distances in a line directly off shore ; repeated for half an hour.

Noted :—

1. Daboll's Horn.—Pressure of air, 10 lbs. to square inch.
2. Gun.—Description : 18-pounder ; weight, 22 cwt. ; charge of powder. 3 lbs.

No. 3.—Bell ; weight, 10 cwt. ; diameter, 37 inches.

Bearings of lighthouse for Series No. 1, N. ; No. 2, E.N.E. ; and No. 3, W.S.W.

State of Weather.—Calm, with variable flaws all ways.

From 1 to 1.15 p.m.—Lighthouse bearing north 1 mile ; light air from the westward ; very smooth water ; paddles stopped.
Daboll's horn heard but indistinctly.
Gun sounded like a musket.
Bell more distinct than either horn or gun.
Bell and horn both going together ; horn most distinct

From 1.15 to 1.24 p.m.—Lighthouse on same bearing ; weather calm.
Daboll's horn heard much better than before.
Gun sounded better also.
Bell very good ; almost equal to the horn.
Bell and horn together ; horn had the advantage.
With the paddles going, neither heard very distinctly.

At 1.30 p.m.—Lighthouse on the same bearing, two miles off. Weather calm, with the paddles going. The flash and smoke of gun were seen, but no report heard. Paddles stopped.
Bell barely heard.
Bell and horn both going together ; horn had the advantage.

At 1.36 p.m.—Horn alone ; very fair.

At 1.39 p.m.—Gun ; very good.

At 1.42 p.m.—Bell ; faintly audible.

At 1.45 p.m.—Bell and horn together ; both very indistinctly heard, but equal in sound.

At 1.48 p.m.—Horn only once in three minutes ; indistinctly heard.

At 1.51 p.m.—Gun ; very good.

At 1.54 p.m.—Bell ; just audible.

At 1.57 p.m.—Horn and bell together ; the horn very good.
Bell only just audible.

At 2.6 p.m.—Lighthouse still bearing north, but three miles off ; very light air from the eastward, almost calm.
With the paddles going, the flash and smoke of the gun were seen, but no report heard.
Paddles stopped.
Bell not heard.

At 2.9 p.m.—Horn faintly heard, but good for the distance.

At 2.12 p.m.—Horn distinct, and marked.

At 2.15 p.m.—Report of gun very good.

At 2.24 p.m.—Lighthouse on same bearing, four miles off.
Horn not heard.

At 2.27 p.m.—Gun heard faintly.

At 2.30 p.m.—Bell not heard.

At 2.30 p.m.—Turned round and steamed in towards the lighthouse, and stopped at 3½ miles off.
Horn heard very faintly.
Bell not heard at all.
Proceeded in to 2½ miles.

At 2.52 p.m.—Horn heard very fairly.
Bell very indistinctly heard.
Proceeded in, and sent a boat on shore, with instructions for the experiments to be repeated.

At 3.30 p.m.—Calm ; lighthouse bearing N.E. by E. ½ E. one mile ; stopped.
Bell very distinctly heard.
Horn the same.
Steamed on to the westward, lighthouse bearing E.N.E., distant two miles.

At 3.40 p.m.—Gun pretty good, with the paddles just moving.
Paddles stopped.
Bell faint, but not continuous.
Horn faint.
Gun very distinct.

At 4.33 p.m.—Proceeded to the eastward, lighthouse W. by S. ½ S., one mile ; light south-easterly air.
Gun very distinct.
Bell very good.
Horn not so good as bell.
Proceeded on to the eastward ; lighthouse S.W. by W. two miles.

At 4.47 p.m.—Bell distinct, but not continuous.
Horn very faintly heard.
Gun very distinct.

The committee having submitted the detail of these experiments, would record their unanimous opinion as follows :—

That the gun was proved to be the best warning signal.

That the fog-horn in its line of axis has an advantage of one mile beyond the bell.

That out of that line, at a distance varying from one to two miles, the horn and bell were on an equality.

That the fog-horn in calm weather may be considered in its line of axis to have a range of 3½ miles, but out of that line not more than two miles.

That the bell in similar weather would give a good warning sound all round, to the distance of two miles ; or,

That either horn or bell would furnish sufficient intimation of danger to a sailing vessel ; but that for a steamer with her paddles going, neither gun, horn, or bell would be of the slightest advantage, except at a short distance.

The Secretary, Marine Department, Board of Trade, to the Secretary, Trinity House.

Board of Trade, Whitehall, Feb. 15, 1864.

Sir,—I am directed by the Lords of the Committee of Privy Council for Trade to acknowledge the receipt of your letter of the 3rd instant, and, in reply, to acquaint you, for the information of the Elder Brethren, that the Board of Trade sanctions the purchase of one of Daboll's 32-inch fog-trumpets for the sum of £950, as recommended in your letter.

I am, at the same time, to request you to direct the attention of the Elder Brethren to some points which are essential to a thorough investigation of the practical merits of this machine.

It is evident, from the trials which have already been made, that the effective power of the trumpet is very seriously diminished when passing away from the line of the axis or mouth ; so much so, that whereas it was distinctly heard at a distance of two and a half miles, when the Trinity House steamer was in the favourable position, it was necessary to approach within one-third of a mile when the vessel was at right angles to the axis of the trumpet. This is a serious defect ; for whilst the trumpet, with its axis directed out to sea, might be heard distinctly by passing vessels, others might approach it on either side, and run ashore in the adjacent bights of the coast without receiving any warning. But probably this defect could be remedied, and it might be possible to contrive that the trumpet should revolve in an arc, so as to throw its whole or maximum sound seaward round the horizon.

The Board of Trade would also be glad to be informed if any experiments have been or can be made with a fog-trumpet at the height of 100 or 200 feet, and in a dense fog, in order to ascertain how its sound is, under these circumstances, projected over the sea. It is well known that a dense fog often affects sound, and renders it difficult to ascertain the direction from which it proceeds, and it is possible that a fog-trumpet, by throwing its maximum sound in one direction only, may occasion very deceptive conclusions.

The Board of Trade would be glad to be informed of the result of the investigation of these points by the Elder Brethren.—I am, &c.,

To the Secretary, Trinity House. (Signed) T. H. Farrer.

CORRESPONDENCE.

BONELLI'S TELEGRAPH COMPANY.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—In replying to my remarks made on the shortcomings of Bonelli's multiple wire system, "Henry Cook" presumes on his own convictions.

When stating that from five to nine wires were employed, I certainly might have said from five to thirteen; for every odd number, from thirteen down to five, seems to have been proposed and tried. (See *Record of Practical Mechanic's Journal on Exhibition*, 1862; *Fleeming Jenkin's Report*, &c.)

Five times the length of wire costs every farthing five times the amount of single length, so do the insulators; and only H. C. could suppose I meant to put five times the number of posts also; still he incorrectly gives the price as rather under double. It will be quite two and a half times that of a single line, and then no provision is made for stronger posts, which he ought to have. But how about maintenance? H. C., no doubt, does that gratis altogether.

I do not believe Bonelli's instrument can do as much with their five wires as Hughes', Wheatstone's, Siemens', and others, do with two—nor will H. C., by mere assertion, persuade me into such a belief; and I further most seriously question the *necessity* of a Roman type telegraph. Encourage compositors to study the Morse alphabet by an extra half-a-crown per week, and they will go to work with the Morse strips as fast as with Bonelli's.

About the fearful chances against the efficiency of the line which H. C. appears to consider *nil*, I will only add this much. Experience has taught some of us—and any rudimentary treatise on the history and progress of telegraphy may teach the rest—that a dozen of systems, as beautifully conceived as Sig. Bonelli's, have gone into oblivion because they required too many line wires.—I remain, &c., G. R.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—Perhaps a few lines from one who was present on the occasion of Mr. Cook's lecture on the "Bonelli Instrument," and conversant with the subject, may not be out of place. There is no science so little understood by the public as telegraphy, and nothing is more easy than to exhibit an instrument in a room, and to produce seemingly wonderful results (which, however, were not arrived at on Tuesday); but it is an entirely different matter in practice.

The drawback to Bonelli's instrument is, that it requires five wires to work it, and there are no two towns in the United Kingdom, except, perhaps, Liverpool and London, where five wires are wanted; and even between those points, in order to avoid repetitions, I understand that the wires are led into different places, and the messages are sent without a break; but on the Bonelli's system all the messages would have to be forwarded to one station and thence retransmitted, causing a liability to error and considerable delay. In order to send messages at the same moment, say, to Cork, Queenstown, Limerick, and Waterford, as is, I believe, done at present with one wire to each town, Bonelli would require five wires to each town,—in all, 20 wires to do that which is now accomplished with four wires; and the cost of construction and maintenance of the lines would be increased in nearly the same proportion.

In the case of a break-down (and these occur frequently on telegraph lines) the Bonelli company would, I presume, use some other description of instrument, so that the 8*s*. per week type-setters, alluded to by Mr. Cook in his lecture, would be useless, and the company would require to have a highly paid staff at each station in reserve.

With regard to speed and accuracy, a signal, in my opinion, can be sent much quicker by telegraph than the most experienced compositor can set up type; and it is just as likely that a type-setter may make a mistake from the manuscript as that a clerk would send a wrong word.

It was elicited from Mr. Cook that the Bonelli Company intend only to use the Bonelli instruments between the large towns, and the company would, therefore, require to avail themselves of another system of telegraph, which must necessarily add to the cost of working, and greatly interfere with their operations.—I am, sir, your obedient servant,

April 27. CIVIS.

TELEGRAPHIC NEWS.

THE MAGNETIC TELEGRAPH COMPANY.—We understand that the above company have entered into working arrangements with the South Eastern Railway Telegraph Company. Messages can now be transmitted direct through both company's wires to all parts.

THE MADRAS AND BANGALORE TELEGRAPH.—From the report of the Madras Railway Company, we learn that the telegraph line in the south-west district is in good working order, and that Bangalore has been placed in immediate communication with Madras.

THE SUBMARINE TELEGRAPH COMPANY.—This company has arranged to open a branch office at 43, Regent Circus, the west-end business of the company having hitherto been carried on at the office of the Magnetic Telegraph Company. The office will be open for messages daily from 8 A.M. to 12 P.M.

COMMUNICATION BETWEEN LONDON AND SIBERIA.—During the last twelve months a line of telegraph has been opened between London and Tuvnen, in Siberia, a distance of 4,039 miles overland. The continuation to Nicolaiwski, on the Pacific, is now probably accomplished; and the connexion, viâ California, with New York is confidently looked for in the ensuing year.

ELECTRIC AND INTERNATIONAL TELEGRAPH COMPANY.—Two lines of pneumatic tubing for the transmission of telegraph messages are being laid between the above company's chief station in Castle-street and the two branch offices in Water-street and Royal Exchange-buildings, Liverpool. The pipes are 2½ inches in diameter, and are to be worked by a novel pneumatic arrangement introduced by Mr. Varley, a full description of which will be given in a future number.

PERSIAN GULF CABLE.—Her Majesty's ship Dalhousie sailed from Bombay for Mussendom on the 16th March, with the Euphrates and Constance in tow, loaded with plant for the various stations. The whole telegraph fleet will then have left our harbour for the Gulf, with the exception of the steamer Amberwitch, which will follow as soon as she comes out of dock. It is stated that Persia has objected to the line of telegraph being carried along the coast of Mekran, and expresses herself disinclined to respect any treaty we may have with the Sultan of Muscat. We are not aware on what authority this information is given, but under any circumstances England is not likely to yield to a claim which the local chiefs repudiate, and which there is every reason to suppose the Shah of Persia could not make good. The territory of Gwadel, concerning which the difference is said to have arisen, is under the authority of the Sultan of Muscat; with him our arrangements have been made, and we can scarcely believe that Persia will be imprudent enough to attempt to interfere with them. It is always well to let sleeping dogs lie.

THE UNITED KINGDOM AND BONELLI COMPANIES' PROPOSED COMPETITION.—Since our last issue the following correspondence has appeared in the daily journals upon this subject:—United Kingdom Electric Telegraph Company, April 30, 1864.—Dear Sir,—In reply to your letter of the 28th inst., I beg to state that your company accepted the challenge of this company, which I again quote, as follows, viz.:—"The Directors of the United Kingdom Company challenge the Bonelli Company to a competitive trial of the system they propose with the system of the United Kingdom Company between Liverpool and Manchester, and are prepared to prove the Bonelli system, wire for wire, to be slower, infinitely more costly, and from the number of wires required, impracticable."—You now say that you cannot come to terms, because the conditions this company proposes are inadmissible, and because this company proposes to try the ink-writing Morse, although at the time you accepted the challenge you perfectly well knew that at present that instrument formed the largest part of this company's system. As the trial of the Morse would entail trouble only on this company, and would not interfere with your part of the trial in any shape or way, why do you object at present to compete with it? You state that you shall proceed to work out the terms you proposed to this company, which your directors consider a fair basis. These, irrespective of apparatus, were as follows:—You proposed to us to work with five wires, thus asking us to adopt an objectional feature of your system. You proposed that each company might call for the other company's wires—a condition which we, with our extensive business, manifestly could not comply with. You proposed that, if an error occurred in a message, the message should be repeated again and again until correct—a great disadvantage of your system, which we declined to make our own, seeing that on either of our systems an error is instantaneously corrected. You proposed no certain period over which the trial should extend, and expressly provided that the experiments might be stopped at any moment at the discretion of the umpires, practically unacquainted with the working. You proposed no arrangement whatever upon that part of our challenge to prove the "impracticability" of using an instrument that cannot work with less than five wires, and you evidently imagined that this did not apply to "commercial" as well as to "mechanical" impracticability. This company, on the other hand, desired experiments extending over a lengthened period, several hundred messages per day, and newspaper expresses, to be forwarded. The apparatus, staff, and expense to be fixed beforehand. The mechanical, electrical, and chemical appliances to be explained beforehand, and no departure from the basis so settled to be permitted. That no other instruments should be employed to convey instructions, or to assist to correct any faults in the apparatus under trial. We proposed to take the basis of your own prospectus for the work to be done, and for proof of the statements made in that document as to what your company have accomplished up to this time on your line from Liverpool to Manchester. Nothing, surely, could be fairer or more indulgent to your company than to take your own statements, and give you the opportunity of proving them. The worshipful the mayors or presidents of the chambers of commerce to be appointed umpires. Comparing other mechanical transmitters with that of the Bonelli Company, their inventors, using only one wire, claim far higher comparative rates of speed than the Bonelli Company, and yet it has not been found practicable to bring these apparatus into actual use. I refer the public to our proposals advertised in the *Daily News, Standard*, and *Telegraph* of the 26th, and *The Times* of the 27th of April. The public reading these will be enabled to judge which company desired a real *bona fide* trial. I would simply observe that this company is still prepared to

carry out the challenge given, and that, as we are much occupied just now in opening the large towns, a week's notice from you shall at any time find us ready to carry out this challenge, accepted by you, but now shunned. As regards the experiments you state that you are going to make, it has been open to your company to make them at any time since your line was erected, and that they are now again necessary is, I submit, proof sufficient that the public, best able to judge—viz., the telegraphing public of Liverpool and Manchester, has not encouraged the extension of the operations of your company. No more experiments that your company can make will satisfy the public, who can only be convinced by the results of an exhaustive trial to bring out the economical, mechanical, and electrical merits or demerits of the respective systems under the eyes of practical men fully alive to the commercial and practical merits of telegraphic systems, and thoroughly conversant with the economy and working of a telegraph company. You now decline to undergo the ordeal of such a trial, and until you are prepared to do so I must decline any further correspondence, and shall be perfectly satisfied to leave the public to judge between us.—W. ANDREWS, Secretary and Manager.—J. Gutteres, Esq.

MISCELLANEA.

TAR, A NON-CONDUCTOR.—A correspondent connected with one of our telegraph companies informs us that coal tar is a good non-conductor, and an excellent preservative for telegraph posts, but when applied cold it washes off. As it is difficult and inconvenient to apply it hot for such purposes, he desires us to call the attention of inventors to this subject, in order that they may make efforts to combine some other substance with it, so as to apply it cold and render it permanently adhesive.

TERRESTRIAL MAGNETISM.—Dr. Faraday has proved that all the phenomena of revolving plates may be produced by the inductive action of the earth's magnetism alone. If a copper plate be connected with a galvanometer by two copper wires, one from the centre and another from the circumference in order to collect and convey the electricity, it is found that when the plate revolves in a plane passing through the line of the dip the galvanometer is not affected. But as soon as the plate is inclined to that plane, electricity begins to be developed by its rotation; it becomes more powerful as the inclination increases, and arrives at a maximum when the plate revolves at right angles to the line of the dip. When the revolution is in the same direction with that of the hands of a watch, the current of electricity flows from its centre to its circumference; and when the rotation is in the opposite direction, the current sets the contrary way. The greatest deviation of the galvanometer amounted to 50° or 60° when the direction of the rotation was accommodated to the oscillation of the needle. Thus a copper plate revolving in a plane at right angles to the line of the dip forms a new electrical machine, differing from the common plate-glass machine by the material of which it is composed being the most perfect conductor, whereas glass is one of the most perfect non-conductors: besides, insulation, which is essential in the glass machine, is fatal in the copper one. The quantity of electricity evolved by the metal does not appear to be inferior to that developed by the glass, though very different in intensity.

THE THERMO-PILE OF SEEBECK AND MELLONI FOR MEASURING HEAT.—This instrument consists of a bundle of bars of bismuth and antimony, the single bars separated from each other by gypsum or some other non-conductor of electricity, but soldered together alternately at their ends. The two end-pieces of this so-called pile are connected with the copper wire of a galvanometer. Rays of heat impinging on one of the faces of the thermo-pile, develope in the latter an electric current, which during its passage through the copper wire deflects the magnetic needle of the galvanometer. An increase of the heat would augment the deflection of the needle. If we suppose our source of heat and its distance from the pile so chosen, that the radiant heat after passing through an exhausted tube would cause a deflection of 10° of the needle, then admission of an absorbing gas would cut off some of the rays of heat, and the needle would recede to a proportionate extent. We will assume the needle to point to $9\frac{9}{10}°$ after admission of air. A difference of $\frac{1}{10}°$ could scarcely be appreciated, and would therefore be a very doubtful result. The absolute amount of heat to cause the needle to move through an arc of 10° is very small. A more powerful flux of heat would increase the deflection and also the absorption. If we suppose the needle to have been deflected 81° by radiant heat passing through an exhausted tube, an absorption of 1 per cent. of this amount could scarcely be detected by retrograde movement of the needle, for it requires much more heat to move the needle from 80° to 81°, than from 9° to 10°; the galvanometer is more sensitive when the needle is near zero. Hence, if the instrument could be kept in this sensitive condition, whilst the substances to be examined are exposed to a very powerful flux of heat, the attending absorption might be detected. If the needle of the galvanometer is in its normal position, heat, which falls on one side of the thermo-pile, will always cause a deflection in the same direction; but if the heat is allowed to meet the opposite face of the pile, a deflection opposite in direction to the former will result. Therefore, if equal quantities of heat fall simultaneously on both sides of the pile, the effect produced by the one source will be counterbalanced by the equal effect of the other source, and the needle will remain at zero.

HEAT.—The application of heat to the various branches of the mechanical and chemical arts has, within a few years, effected a greater change in the condition of man than had been accomplished in any equal period of its existence. Armed, by the expansion and condensation of fluids, with a power equal to that of the lightning itself, conquering time and space, he flies over plains and travels on paths cut by human industry, even through mountains, with a velocity and smoothness more like planetary than terrestrial motion; he crosses the deep in opposition to wind and tide; by releasing the strain of the cable, he rides at anchor fearless of the storm; he makes the elements of air and water the carriers of warmth, not only to banish winter from his home but to adorn it even during the snow storm with the blossoms of his spring; and, like a magician, he arises from the gloomy and deep abyss of the mine the spirit of light to dispel the midnight darkness.

TO CORRESPONDENTS.

As information respecting Improvements, Extension of Lines, and Progress of New Undertakings will at all times be most acceptable, we hope that our readers will kindly render us assistance in our efforts to establish a Journal worthy in all respects of the great interest it seeks to represent, by furnishing us with brief notices of events and occurrences in connection with Telegraphy.

Communications intended for publication must be authenticated by the names and addresses of the writers; not neccessarily for insertion.

Letters relating to Advertisements are to be addressed to the Publishers. All other letters and communications to be addressed to the Editor of the *Telegraphic Journal*, 5, Suffolk-lane, Cannon-street, London, E.C.

Advertisements must be delivered to ensure insertion before SEVEN O'CLOCK on Thursday evening in each week. The charges for Advertisements are—

	£.	s.	d.
Whole page	4	4	0
Half ditto	2	10	0
Quarter ditto	1	7	6
Four lines and under (single column)	0	3	0

The *Telegraphic Journal* is the most effective medium for inventors, patentees, contractors, manufacturers of insulating materials and electrical apparatus to submit their various specialities to the consideration of secretaries and managers of telegraph or railway companies, and other persons engaged in electrical and telegraphic pursuits.

Clerks, assistants, manipulators, and instrument makers, seeking employment, &c., will find the *Telegraphic Journal* a ready means of making known their requirements.

TELEGRAPHIC COMMUNICATION BETWEEN INDIA AND AUSTRALIA.

THE success which has attended telegraphic operations in the Persian Gulf has again revived the important subject of telegraphic communication to Australia. From the "Copy of Correspondence and Papers relating to the Establishment of Telegraphic Communication between India, Singapore, and Australia," recently printed by order of the House of Commons, a considerable amount of information will be derived upon the subject. It appears that Mr. F. Gisborne, who in 1859-60 went to Australia on the behalf of the promoters of the Anglo-Australian telegraph, made considerable progress towards the realisation of the great and desirable project, so far, that several of the colonies voted subsidies amounting to some £25,000 per annum, and further steps were taken to complete the amount to £35,000, and to set the undertaking on foot; but, however, owing to the failure of the Red Sea lines, and the incomplete state of telegraphic communication from Constantinople to Bagdad and Bussorah, and from thence to Kurrachee, the promoters of the Anglo-Australian telegraphs were deterred from proceeding further in the matter; and besides, the decision of the Government to change the destination of the then newly manufactured Rangoon and Singapore cable placed additional difficulties in the way of the promoters.

The proposed line is of considerable length, as will be found from the following measurements, and consist almost entirely of submarine links:—

	Nautical Miles.
Rangoon to Mergui	400
Mergui to Penang	400
Penang to Singapore	360
Singapore to Cape Sedano	1,160
Cape Sedano to Timor	590
Timor to Port Essington	525
Port Essington to Cape York	625
Cape York to Cleveland Bay	619
Cleveland Bay to Moreton Bay	655
Moreton Bay to Sydney (land line)	600

Captain Denham, of her Majesty's ship Herald, in reporting the result of his survey of the proposed line from Cape Sedano, in East Java, where the Dutch line from Singapore terminates, to Cape Cork, states:—"Nothing could be more favourable for an electric cable-bed than the depth and bottom of the Arafura Sea (17 to 50 fathoms very gradually and upon mud), until you get abreast (17 miles distance) of Cape York. * * * A cable might be laid in-shore of my track connecting Java with Timor by a line down Baly Strait, where I found 282 fathoms up sand; then along the southern-face offing of Landbach, Sombara, and Flores, to Koepang; then by land to the north-east extreme of Timor; whence and oblique east by south submarine direction across the Arafura Sea by Cape Wessel to Cape York, or a station upon the eastern side of Cape Carpentaria, where your Excellency's Government would consummate the enterprise. This would comprise 1,600 miles of distance, and require 2,000 miles of cable between Australia and Java."

As it is our intention to refer to the contents of this important Parliamentary paper in our next number, we extract the following statement made by the promoters, and submitted by them to the Colonial and Home Governments:—

The objects of the promoters, who represent forty banks and firms trading with China and Australia, are to establish telegraphic communication between India and Australia, and between India and China, the effect of which will be to bring Australia and China into nearly instantaneous communication with India and with each other, and within, say, sixteen days of Great Britain, besides converting the communication, which is now once a month only to Australia and once a fortnight to China, into a weekly one to each country. When telegraphic communication is re-established between Egypt, or Turkey in Asia, and India, the communication between Great Britain, China, and Australia will be further reduced from sixteen days to about as many hours.

To carry out these objects, it will be necessary to construct three lines of telegraph:—

1. To lay a submarine cable to connect Singapore with the telegraph system of India at Rangoon, the present terminus of that system, over a distance of 1,200 sea miles, with intermediate stations at Amherst (Moulmein), King Island, and Penang.

2. To extend the cable from Singapore to Hong Kong (Canton), viâ Sarawak, Labuan, and Manilla, a distance of 2,080 miles, or viâ the French settlement of Saigon, a distance of 1,678 miles.

3. To extend the Dutch lines which connect Singapore with Batavia and the east end of Java, from that point to the terminus of the telegraphic system of Australia, which at present is at Brisbane, on the eastern coast, but which is likely to be soon carried further northward.

The distance from Java to Brisbane, viâ Timor and the Northern Coast of Australia, is 3,024 miles.

Soundings have been taken between Rangoon, Singapore and Hong Kong, also between Java and Brisbane, and they show that the different cables can be laid on a soft and uniform sea-bottom, seldom exceeding 50 fathoms in depth.

The numerous islands of these seas will enable stations to be placed about 600 miles apart—a convenient distance for working and repairs.

The Malta and Alexandria cable, which is longer than the proposed India-Singapore, and nearly half the length of the Java-Brisbane line, in common with nearly every other cable laid in shallow water, or say within 100 fathoms, has been maintained in permanent good working order. At this moment there are more than 3,000 nautical miles of cable, containing upwards of 5,000 miles of insulated wire, successfully at work in shallow water; some have worked for eight or ten years, and a large proportion have cost nothing for repairs. Occasional interruptions are the only dangers to be feared; and when an efficient steamer is maintained for the purpose, any necessary repairs can be rapidly and easily effected.

The promoters have applied to the Government of India for an annual subsidy in support of the India-Singapore, or first section. Sir Charles Wood assured a deputation of the promoters that the Indian Government would carry out, or assist in carrying out, this section contemporaneously with the other sections.

They have applied to the Government for an annual subsidy for that portion of the second section which is between Singapore and Saigon.

The Australian Legislatures voted considerable subsidies two years ago in support of the Java-Queensland, or third section, and they have been asked to apply them to carrying out the work at once.

All these subsidies are only to run during the successful working of the lines; but a reasonable time in each year is to be allowed for repairs, without any deduction in the payments. The Company will always have a steamer in readiness to effect any repairs which may be required.

The Singapore-Batavia line has been frequently interrupted. These interruptions have been due partly to the light cable used, and have been unnecessarily prolonged, owing to the absence of any organization for repairs; but the Dutch Government will have a strong interest in keeping up this telegraphic communication efficiently, so soon as Singapore is connected with India. They have granted the right to the promoters to have a separate wire through Java, and to settle the tariff of messages in conjunction with the Government.

Arrangements are in progress for securing an efficient cable between Batavia-Singapore.

It appears from official returns that 10,000 vessels, including repeated voyages, and a trade of £64,000,000 at the least, will annually make use of the line between India and China, and that a trade of £40,000,000, in which 2,400 vessels are engaged, will annually make use of that between India and Australia. The trade, moreover, both with China and Australia, is rapidly on the increase, and a large and wealthy population in the latter country will send and receive numerous messages on private business. From

these sources it is estimated that a minimum of 40,000 messages will be annually transmitted by the cable between India and China, and a similar number by that between India and Australia, principally on their way to and from Europe, being 55 messages per diem each way to and from China and Australia respectively.

The relative cost of the three sections will be as follows:—

Rangoon-Singapore	£450,000
Singapore-Hong Kong	530,000
Java-Brisbane	1,100,000
Total	£2,080,000
Singapore to Java (subsidy of £8,500 per annum given by Dutch Government)	170,000
TOTAL	£2,250,000

This capital includes a sufficient reserve fund, and will provide heavy cables, protected against corrosion by a hard bituminous outer covering. The cables will be capable of transmitting over 70,000 messages, of twenty words each, per annum, with the ordinary instruments now in use. For the India-Singapore section a larger core will be adopted, capable of transmitting 150,000 messages per annum. This number of messages could be doubled by adopting the latest improvements in instruments.

The negotiations between the promoters and the Australian Governments, in reference to the line between Java and Queensland, have been carried on as follows:—Mr. F. Gisborne proceeded to Australia in 1860, for the purpose of obtaining subsidies for that line. New South Wales voted a subsidy of £10,000 per annum, without requiring the Home Government to contribute. Victoria voted £13,000 a-year, contingent upon the Home Government contributing something; and the Governments of Tasmania, New Zealand, and Queensland promised proportionate contributions. Subsequently Victoria made an offer to the Home Government to provide half of the whole subsidy that might be required, if the Home Government would also provide half. It was understood at the time that Victoria would take Tasmania, South Australia, and Western Australia as her co-contributors, leaving New South Wales, Queensland, and New Zealand as co-contributors with the Home Government, which would practically reduce the contribution of the Home Government to a trifling amount. The whole annual subsidy then asked for was £35,000 to raise a capital of £800,000. This was calculated to provide a cable similar to that then recently laid in the Red Sea, and between Batavia and Singapore. The outer iron covering of this cable, however, has since proved very much too light, and liable to corrosion. The greater part of the Red Sea cable was laid in deep water, where it was impossible to repair it. The failure of this and other deep sea cables made it impossible for some time to act upon the resolutions passed by the Australian Legislatures. The public did not at first discriminate between deep and shallow sea cables, but the obvious and continued success of the great majority of shallow sea lines, and especially of the long cable between Malta and Alexandria, has revived public confidence in those undertakings. It is now proposed to lay a cable three and a half times the weight of that laid in the Red Sea, and moreover, protected against corrosion by a hard bituminous outer covering, which has been successfully applied to cables in the English and Irish Channels.

To lay this heavier cable, it will be necessary to increase the capital to £1,100,000. The subsidy would thus be raised to £50,000 per annum, on the basis already adopted in the resolutions passed by the Legislatures of New South Wales and Victoria, in 1860.

The subsidy is to run for thirty years. The promoters offer to transmit the messages of the Colonial and Home Governments without payment to the extent of the subsidy, and in case the Home Government does not contribute, to place the tariff value of their messages to the credit of the subsidy, so that the difference only should be paid by the Colonies. It is estimated that 40,000 additional messages will be brought annually upon the telegraphs in Australia by the subsidised line, which will be a considerable source of revenue towards paying the subsidy.

The promoters ask that Victoria and New South Wales shall render themselves liable to the Company for the whole subsidy. The liability will be equitably redistributed by means of an intercolonial agreement, basing the contribution of each Colony towards the whole subsidy on the use it shall make of the subsidised line. Thus, if Victoria sends and receives half of the whole number of messages transmitted through that line in any year, it would pay the half of the subsidy. The payment of the subsidy is to be contingent upon the successful working of the cable. Should the Government of Queensland extend its telegraphs to a point north of Brisbane, for instance, to Broad Sound, the Company's cable might be made to terminate at such point; but any such extension must be completed by the end of 1864, and will not diminish the number of stations or the total working expenses, though it will save 350 miles of sea line.

The cable between Java and Brisbane could be laid in about two years after the letting of the contract.

It is proposed to give the Colonies an efficient control over the tariff. Under existing arrangements no tariff can be established anywhere between Malta and Java, without the assent of the British Government.

As regards the contribution of the Home Government, it should be borne in mind that her Majesty's Government has bound itself to complete the telegraph lines as far as Singapore, and will no doubt assist the telegraph to Australia, by lending ships to take additional soundings, and to pilot the cable expedition. It should also be remembered that only one-fifth of the line, the section, namely, between Java and Timor, is out of Australian waters.

LEWIS'S PERMUTATING TELEGRAPH SWITCH.

IN central or way telegraph offices, where any considerable number of different lines or wires have their termini, it is frequently necessary to place the various conductors in communication, so that messages may be continuously transmitted from one city to another without stoppage or re-writing at the central office. This union is generally effected by means of a "switch," which consists of a pivoted bar of metal, so made that on being properly turned it will form a conducting medium to bring a pair of wires or lines into electrical communication.

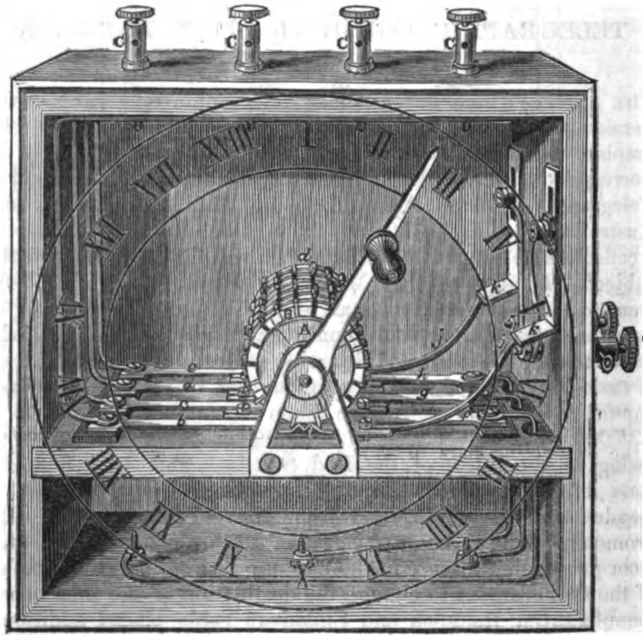

FIG. 1.

Our engravings illustrate a very ingenious improvement by which a single instrument may be made to serve the useful purposes of a large number of the ordinary switch devices. A is a small cylinder of some non-conducting material. Extending across its surface, fastened in grooves, is a series of conducting or connecting bars, B, having teeth, *a*, projecting from them, as shown in Fig. 2. The termini of the different wires or telegraph lines are made in the form of flat springs, *b*, *c*, *d*, *e*, *f*, *g*, *h*, and they are arranged directly under the cylinder, A, towards which they press. In our engraving the springs at the left are attached to the wires which extend up to the screw cups, C, upon the case. The springs at the right pertain to wires that lead below to screw cups under the case, and may connect with the relay instrument, sounder, ground plate or battery.

It will now be apparent that the several springs are, practically,

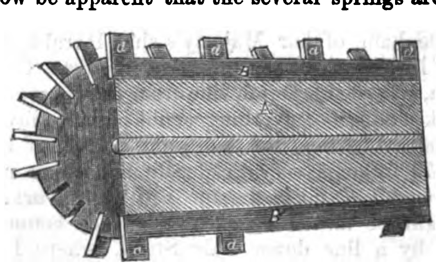

FIG. 2.

so many terminations of electrical conductors or telegraph wires, and the several bars, B, serve to form connections between the said

wires, for the electric fluid will pass along the bars, B, from one spring or wire to another. The bars, B, having been suitably arranged on the surface of the cylinder, may be made to make any desired connections between two or more of the springs. These connections may be established or changed by rotating the cylinder, so as to bring a new bar into contact with the springs. The cylinder is rotated by means of the pointer which traverses a dial face upon the exterior of the instrument. Each number upon this dial indicates to the operator a certain pre-arranged set or combination of connections between the springs. If, for example, the pointer is set at III. it may indicate that wires between New Haven, Philadelphia, and Albany are connected; if the pointer

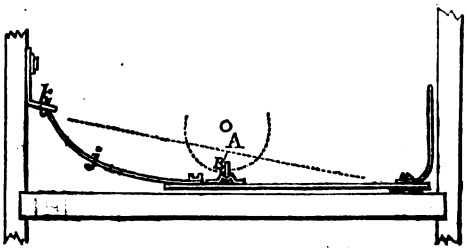

FIG. 3.

is now moved to VI. the cylinder is also turned, and a new connecting-bar, B, is brought into contact with the springs, which may connect the wires between New York, Boston, Washington and Buffalo, and so on. The number of permutations of which a small instrument like this is susceptible is very great, and its extensive utility must be obvious. These permutations may be increased by enlarging the cylinder or by employing two or more cylinders in the same instrument.

The springs are provided at *i* with notches to receive the teeth of the connecting bars, as shown in Fig. 3. The notches serve to hold the cylinder in whatever position it is set by the operator; but the pressure of the springs against the teeth is not great, consequently the cylinder may be readily changed in its position, by moving the dial pointer. The friction of the inclined sides of the notches, *i*, keeps the parts always bright. The several extremities of the springs are forked, and in the fork of each there is a screw stop, which serves as a guide and also prevents the springs from rising too far; contact with the cylinder, when it is so turned that none of the springs are acted upon by the projections, *a*, is thus prevented.

The length of the springs may be increased, if desirable, by the attachment to them of curved parts, *j j*. The extremities of these curved parts press against the under side of the metallic plates, *k*; and these plates are connected to wires leading to any desired screw cup. Two examples of this mode of extending the springs are shown at the right, in the engraving. See also Fig. 3.

The inventor claims:—1. The cylinder and the connecting bars, or their equivalent devices. 2. The springs acting against the barrel. 3. The alternate arrangement of the springs. 4. The notches, with inclined edges, upon the springs. 5. The mode of limiting the upward movement of the springs. 6. The combination of the cylinder with its connecting bars, and the springs with the dial and pointer. These constitute the principal features of the invention, as illustrated in our engraving; and they appear to be very broadly covered by the patent.

This invention has been patented by James Lewis, who may be addressed for further information at Mohawk, Herkimer county, N. Y.—*Scientific American.*

ELECTRO-MAGNETIC PENDULUM.—The principal object of the inventors, Messrs. Hamblet and Edwards, of Boston, U.S., is to apply the pendulum power obtained from an electro-magnet, in order to maintain and also, if desired, to initiate its motion without subjecting it to the direct attraction of the magnet, or in any way attaching to it an armature or fixed magnet, or any piece of metal subject to the attraction of a magnet. The invention consists chiefly in the employment of wedge-shaped pallets in combination with the armature of the electro-magnet, and with one or more impulse bars and springs, whereby the above result is obtained. It also consists in so applying the said pallets in the circuit in which the electro-magnet is placed, that the opening of the circuit, to produce the necessary intermissions of the current, takes place between the said pallets.

THE PROPOSED COMPETITION BETWEEN THE HUGHES AND BONELLI INSTRUMENTS.

WHENCE emanated the advertisement we noted in the daily journals, awhile ago, announcing:—

CHEAP TELEGRAMS.—A Company is in course of formation to establish an uniform sixpenny rate for telegraph messages, &c.

and promising further particulars in a few days? It has disappeared from the public prints, leaving us in expectancy, and we confess somewhat disappointed at not being able to record a further step in telegraphic progress. It is a curious coincidence, however, that this announcement succeeded, day by day, the advertisement of the Bonelli Company, and was withdrawn simultaneously with the prospectus and form of application for shares in this company. Many persons would be led to believe that this was a *ruse* to create perplexity in the minds of capitalists, and to retard investments in telegraph shares, and especially in those of a new company. If the public is wrong in these conjectures, it will be glad to make the *amende honorable,* on receiving the "further particulars," now long promised.

The advent of the Bonelli Company does not appear to have been received kindly; on the contrary, inventors, manufacturers, and would-be authorities on electrical science were all prepared to prove something that would militate against the success of the project, or else they knew of instruments that would surpass Bonelli's in every particular. The managers of the United Kingdom Telegraph Company appear to have been terrified out of their propriety, and in their determination to nip the new enterprise in the bud, they rushed into print again with their prospectus, resorted to every kind of unavailing opposition, and consummated their folly by throwing down the gauntlet to the telegraphic aspirant to public favour. The form of challenge is immaterial to our present purpose, but as it evinces so large a proportion of assurance, we publish it in this place:—"The Directors of the United Kingdom Company challenge the Bonelli Company to a competitive trial of the system they propose with the system of the United Kingdom Company, between London and Liverpool, and are prepared to prove the Bonelli system, wire for wire, to be slower, infinitely more costly, and from the number of wires required, impracticable." We hardly know whether the directors of the Bonelli Company deserve to be censured for precipitancy, or commended for ingenuousness in accepting this challenge, without having the conditions of competition submitted beforehand; because the framing of a series of rules to be observed in these cases often presents a favourable opportunity for the braggadocio (whether it be an individual or a corporate body) to skulk away when brought to deliberate on its own propositions. The competition, nevertheless, was decided upon, and was to have been commenced upon the lines between Liverpool and Manchester on the 30th ult., but owing to a series of decidedly one-sided propositions having been submitted by the United Kingdom Company, disagreement arose, further correspondence ensued, and delay has resulted. It is to a consideration of these proposals that we intend to devote a little space.

A fair field and no favour is an axiom which obtains in all *rencontres* in which Englishmen engage, and the competition for superiority in the rates of transmission of telegraphic messages must not be an exception to this very excellent law. What then are the conditions insisted on by the United Kingdom Company, for a trial of their systems against the apparatus used by the Bonelli Company? The trial is to be of such a character as to afford really satisfactory evidence of the merits of the respective processes. Well and good. But who is to receive the evidence, witness the experiments, and adjudicate thereon? This question has not been lost sight of by the astute framers of this code, so we find that the Worshipful the Mayors of the aforesaid towns, or the Presidents of the Chambers of Commerce, are to arrange the details of the work to be performed, and to record the results. A very general notion prevails among the educated classes of the community that persons who study the law are better qualified to interpret Blackstone than successful manufacturers of cotton fabrics, or ship-brokers; that those who devote themselves to science are more likely to appreciate the value of scientific research than millionaires; and that engineers are far better able to report upon the nature of any new invention, than others, however lofty their stations, who have paid but little attention to mechanics. We are simple enough to entertain these convictions ourselves, and with all deference to the functionaries whose services are to be put into requisition, are disposed to question the wisdom of the

selections, and to suggest that it would be possible to find a more competent tribunal. It seldom happens that men of science aspire to municipal dignities, and we fear that Mr. Fairbairn (an exception to this rule) would experience the greatest difficulty in finding a coadjutor to his mind among the civic authorities of the queendom. But to proceed: the trials are to be exhaustive, to extend over a period of fourteen days, in all weathers, and, had not delay occurred, were to have been commenced, as before stated, on the 30th April; so we are led to conclude that arrangements had been made with Admiral Fitzroy, for samples of "all weathers" during the period extending from that date to the 13th instant, and certainly, to the present time, the meteorological variations would warrant such an assumption. It is also required that the messages to be sent by both companies, during the trial, shall be *fac similes*. Now, if language conveys any idea at all it is this, that the Bonelli Company is to have a fount of type cast of the same character as that used in Hughes' machine, especially for this competition, a requirement positively preposterous; indeed, so absurd that we incline to the view that the challengers, in their enthusiasm, hardly know what they mean; hence we interpose the suggestion that, instead of all messages being fac similes, they are only required to be verbally identical. When we come to consider the instruments to be employed, and the plans by which it is proposed to estimate the work performed by the several instruments, we are favoured with a lesson in arithmetic untaught by Walkinghame. "As the United Kingdom Company uses for both the Hughes Printer, and the Morse Ink-Writer ["for with *both* of these" says the manager, "will the challenge have to be worked out"] only *one wire* EACH, the results in every case be *multiplied by five* for work performed and cost of performing it, so as to *equal* the *five* wires used by the Bonelli Company," *i.e.*, the United Kingdom Company require that the work of five Morse and five Hughes instruments, with ten wires be allowed them to compete with one of Bonelli's instruments, because in working the latter it is necessary to use five wires. The utter absurdity of the proposition elicited a rejoinder, but it should have served to convince the Bonelli Company that the matter of this challenge, unless given for ulterior purposes, has been a very silly joke from beginning to end. We are inclined to the latter opinion, because in the last announcement of the United Kingdom Company it is plainly stated that these propositions are, like the laws of the Medes and Persians, unalterable, and that if the Bonelli Company do not accede to them, further correspondence will fail to effect any settlement of the claims in dispute.

There are several features in this discussion which must not be passed unnoticed. The inuendoes contained in some of the propositions call for serious animadversion. What have the basis performances of the apparatus, *published in the prospectus of the Bonelli Company*, to do with the merits of the several inventions to be put on trial? Why is this Company to declare its available capital, the amount to be paid for patent right, and other remote particulars? What purpose can be accomplished in the course of the trial by the Bonelli Company showing where its instruments are employed in France? These are matters which the directors of the said Company are prepared, doubtless, to lay before their shareholders at the proper season; but how they can affect the merits of the several inventions, or how, by this information, the United Kingdom Company intend "to prove the Bonelli system, wire for wire, to be slower, infinitely more costly, and from the number of wires required, impracticable," we are at a loss to divine. This controversy was initiated by the United Kingdom Company, and before any practical result has been arrived at, we are naïvely informed by the manager of this Company that, as the Bonelli Company desire more equitable terms for the proposed competition than those submitted, and as he has other business on hand, he he must decline further correspondence, and will be perfectly satisfied to leave the public to judge between them. We can only express our regret that so much valuable time has been lost by the disputants, which might have been profitably employed in furthering the interests of the respective companies, and in meeting the requirements of the public. It is truly pitiable to behold a man, unbereft of reason, resorting to mean artifices to accomplish selfish designs; and it is with kindred feelings that we have witnessed the puerile attempts of the United Kingdom Company to retard the introduction of improvements in the art of electro-telegraphy, because they may probably at some future time affect its interests.

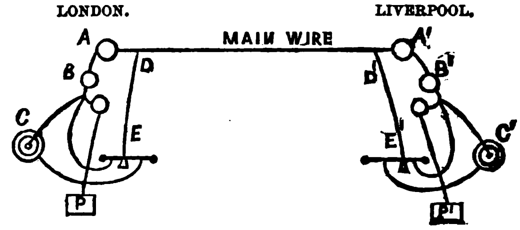
[We cannot endorse all the opinions expressed by our contributor.—ED. T. J.]

THE SIMULTANEOUS TRANSMISSION OF MESSAGES OVER A SINGLE WIRE IN OPPOSITE DIRECTIONS.

CONTRIBUTED BY G. B. PRESCOTT, ESQ.

THE transmission of messages over a single wire in opposite directions at the same instant, had occupied the attention of the scientific, both in Europe and America; and the problem has been solved, in as many different ways, by no less than five individuals. The following drawing illustrates the method devised by Dr. Gintl, of Germany, which seems to be very simple, and proves, upon trial, to work with entire success.



The apparatus used is that of Professor Morse. The arrangement of the circuit is that technically known as the open circuit.

Let me premise that in transmitting a dispatch by this system, the electro-magnet of the transmitting station does not work—only that of the receiving station is operated by the current. When the key, or transmitter, is at rest, a spring closes the connecting point at the back end, and when it is pressed down by the operator in transmitting a message, the back connection is broken, and the front one established.

I have represented a section of line between London and Liverpool. A, A', are two rheostats in the offices of London and Liverpool, which represent, each of them, the exact resistance of the line wire between these two points. B, B', are electro-magnets of peculiar construction, being so arranged that a current may traverse either half or the whole of the coils, or may traverse one coil in one direction, and the other coil in the opposite direction. C, C', are the batteries; E, E', the keys; and P, P', the ground plates.

Let us now suppose that London wishes to send to Liverpool. The operator at London presses down his key, and the current from the battery, C, passes through the key to the main wire, and thence down the branch wire, D', through the key, E', to magnet, B', thence through the ground plates, P' and P, to the magnet, B, and thus back to its starting point in the battery at C. When the current passes through the coil, B', at Liverpool, it operates the apparatus there in the usual manner. But I have not described the entire course of the current. When it reached the junction, D, one half of it passed through the rheostat, A, through the upper half of the magnet, B, and thence to its starting point at the battery. It will thus be seen that one-half of the current having passed in one direction through one of the coils, B, and the other half in the opposite direction through the other coil, B, B', that its effect is neutralised, and that no action takes place in the magnet at the transmitting station.

Now let us suppose that London and Liverpool both press their keys down at the same moment, each sending to the other. The current from the batteries, C and C', would meet at the junction, D and D', and neutralise each other, and, consequently, no current would pass over the wire. It would, in fact, be the same as if the wire were actually broken between these points during the time that both keys were pressed down. Under these circumstances the current from the battery, C, returns through the rheostat, A, through one-half of the coil, B, and thence back to the battery, C. What takes place at London, of course occurs at Liverpool under the same conditions. Thus the writing upon the London and Liverpool instruments is actually performed by their own respective batteries, but as this record depends upon the closing of the key at the distant station, it amounts to the same as if done by the battery of the other.

Having now shown how the record is made while the receiving station has his key in its ordinary position of rest, as well as where it is pressed down in the act of transmitting, let us now consider what will be the course of the current when it is in neither of these positions, that is to say, when the back connection has been broken by pressing the lever to make a letter, but before the front contact

has been established. We will consider that Liverpool's key is in this position, and that London is writing. In this case the current, on arriving at D′, does not pass down the branch wire, as there is no outlet for it, but passes on through the rheostat, A′, thence through both coils, B′, to the ground plate, F′. The current in this case, passes not only along the line between London and Liverpool, but also encounters a resistance at A′, of equal extent; but this is equalised by passing through both coils of the electro-magnet, B′, so that the adjustment of the instrument remains the same throughout.

If this apparatus has not been generally used, it does not arise from its inutility. With a line well constructed, and properly insulated, there would be no difficulty in working it. It could not be relied upon where there is heavy escape, and to have entire success the resistance coils should exactly equal the resistance of the line wire, and the magnets be well constructed.

THE INTERNATIONAL EXHIBITION, 1862.

(Continued from page 223.)

5. *Instruments employed in the production of Statical Electricity.*

C. F. Varley, M. (United Kingdom, 2,981), exhibits an instrument by which very feeble electrical tensions may be multiplied several thousand-fold, so that by its use the tension of the feeblest electrical sources may be demonstrated, and sparks or other analogous phenomena developed from a tension no greater than that produced by the single voltaic cell.* The instrument might be called a multiplying inductor. It consists of an axis on which parallel rows of insulated brass vanes or arms are fixed; the description will be simplified by considering one row of vanes only, A, B, C, D, &c. The axis may be turned by hand, and at two points of the revolution, diametrically opposite to each other, the vanes enter two rows of hollow insulated coverings or shells of brass, a_1 a_1 a_2 a_3, &c., and b_1 b_{11} b_{21} b_3, &c. These shells conceal the vanes entirely on three sides, and are connected one with another as follows: a unconnected, a_1 a_2 joined together, a_3 a_4 joined together, a_5 a_6 joined together, &c. In the opposite row, b b_1 are joined, b_2 b_3 joined, b_4 b_5 joined, &c.; a is opposite b, a_1 opposite b_1, &c. Thus the two rows may be said to be arranged in alternate insulated couples.

The charge to be multiplied is communicated to a, and we will first suppose this charge to consist of a certain definite quantity retained without loss by means of perfect insulation. The axis is next turned round by hand; when the vane A is inside a, an earth connection is made at the inner end of the vane A, where it is not covered by the shell. If the charge on a be positive, a negative charge of corresponding magnitude will be induced on A. The charge so induced may approach more or less nearly, according to the proportions of the instrument, to equality with the charge on a; it will always be somewhat less, but can easily be made in practice to differ very little from the original charge. When the axis is turned round still further, the earth connection is broken, and the negative charge remains insulated on the vane A. As the axis continues to revolve, the vane A is brought inside the shell b, and is then put in connection with the shells b b_1 by a suitable contact. The negative charge on A will then almost entirely distribute itself over the outer surface of the double shell b b_1. As the axis is turned round and round, the same series of contacts will be repeated, successive charges on A will be induced by a and communicated to the double shell b b_1, on the surface of which these charges will gradually accumulate, tending towards a limit which is only not infinite (leaving insulation out of consideration), because, when the vane is inside b b_1, and its contact there made, its whole metal is not surrounded by a closed metal surface forming part of b. The effect will, however, practically be limited rather by imperfect insulation than by the want of continuity in the surrounding surface of b b_1. But while negative electricity is thus accumulating on b b_1, the second vane B has been continually passing through the shell b_1. At the moment when fully covered by this shell, an earth contact has been made with this vane, as already described for vane A. B has therefore been receiving continually greater charges of positive electricity, each very nearly equal to the quantity of negative electricity at that time on b b_1, and these in their turn it has communicated to the shells a_1 a_2. The vane C receives continually-increasing negative charges from a_1 a_2, which it communicates to b_2 b_4, and thus the multiplication proceeds through any required number of vanes and shells by the simple process of turning the axis.

* Professor Wheatstone has pointed out to the writer, that in 1787 and 1788 instruments designed to fulfil the same object were described by Bennett and Nicholson in the "Philosophical Transactions."

If all the vanes and shells be alike, and if one vane with its pair of shells can at most produce a charge in the second shell only ten times greater than that in the first, it is clear that ten vanes and their shells would produce a maximum charge in the final shell 10^{10}, or 10,000,000,000 times greater than that on the first shell. The tension of this final shell, if all disturbing causes be removed, would likewise be 10,000,000,000 times greater than that of the first shell under similar circumstances. Metallic screens in connection with the earth are used between each pair of coupled shells to prevent their action one on the other, and also surrounding the whole apparatus to screen it from irregular electric induction.

If, instead of giving the first shell a a certain definite quantity of electricity, it were maintained at a certain constant potential by contact with a source of electricity (for instance, connected with one pole of a battery, while the other is in connection with the earth), the result would be exactly similar to that which would be obtained if a definite quantity, equal to that contained in the shell a when the vane A is inside it, and the earth contact made, had been communicated to the shell a in the first instance. The actual multiplication for each number of turns would, when the insulation is good, be perfectly definite, but could in this arrangement be practically determined by experiment only; it was understood that Mr. Varley has, by slightly modifying the present arrangement, produced an instrument in which it is easy by calculation to determine the multiplication given by any fixed number of turns.

Peclet with his three-plate condenser has long since given a means by which electrical tensions might be indefinitely multiplied, but the manipulation of his instrument was extremely tedious, and its action notoriously irregular. Svanberg in 1848 described to the British Association a superior arrangement to Peclet's, with which he states that he actually obtained sparks from a single Daniell's cell. The manipulation of Svanberg's apparatus would, however, be very tedious, and unless special precautions were taken in making the successive connections by hand, the results could not be relied on. Mr. Varley's apparatus is extremely simple in its use, and substitutes simple rotation for the complicated series of transfers required by Svanberg and Peclet; it is consequently much more rapid in its action, and on this account alone more certain; all the contacts are made mechanically, and are therefore always made in the same manner; and Mr. Varley so constructs his instrument that the contacts shall always take place between exactly similar pieces of platinum. As a proof that the instrument could be relied on as indicating a real multiplication of the charge originally given to the first plate, Mr. Varley showed the jury a strong positive tension, produced by multiplying the tension of the positive pole of a Daniell's cell by a definite number of rotations of the axis, and then reversing the poles of the battery and turning the axis of the instrument double the number of times used to produce the first tension, he reversed that tension, and produced a very nearly equal tension of the opposite sign. The tensions were strong enough to produce sparks, and were measured on Professor W. Thomson's portable electrometer, exhibited by Mr. White. Mr. Varley has since informed the writer that he has obtained a multiplication of more than 15,000 times the original tension by the use of his instrument. It should be observed that this instrument offers an instance of the direct transformation of work into electrical distribution.

C. Varley (United Kingdom, 2,980) exhibits a fine electrical machine with a vulcanite disc, and with conductors mounted on vulcanite stems. This application of vulcanite is novel since 1851, and gives excellent results, allowing the apparatus to be satisfactorily worked in damp states of the atmosphere, when instruments made with the common glass mountings would be nearly useless. The disc of vulcanite is thirty-five inches in diameter. The amalgam used with this material should be softer than that used with glass, otherwise the disc deteriorates with use. A large induction ring is used on the plan adopted by Dr. Winter, of Vienna. Under favourable circumstances sparks twenty inches in length have been obtained from this instrument. Without Dr. Winter's ring the sparks were reduced to about seven inches.

Elliott Brothers, M. (United Kingdom, 2,897), and S. W. Silver & Co., M. (United Kingdom, 2,960), also exhibit large and good electrical machines with ebonite or vulcanite discs and mountings.

H. Watson, Newcastle (United Kingdom, 2,986), exhibits an Armstrong's hydro-electric machine of the usual form.

6. *Chronoscopes.*

Chronoscopes, or instruments used for the measurement of very short intervals of time, will next be considered. As already mentioned, these instruments are chiefly used for determining the velocity of projectiles. Two screens, made each of a continuous wire led backwards and forwards across a frame, are placed in the path of the ball at a known distance apart. The wires of each screen form part of complete circuits communicating with the instrument; when the wires are successively broken by the projectile the successive interruptions of the two circuits are registered by electrical means on some apparatus, part of which moves with a known velocity. This plan of determining the velocity of a ball is due to Professor Wheatstone.

It is not necessary that the two circuits should be distinct throughout their whole length; the rupture of the circuit containing the first screen by the very cessation of the current through it is easily made by electro-magnetic apparatus, to establish a current through a circuit containing both the second screen and part of the first circuit. By these very simple contrivances, the ball as it successively breaks two circuits, sends as it were two signals by stopping two currents at the very instant that it passes two points of the trajectory, but it is by no means equally easy to *register* the instants at which those signals are sent. The time elapsing between them must be measured by reference to some continuous movement of which the speed is accurately known, and it is very difficult to produce such a movement. Clock-work governed by an escapement can only give a step-by-step or intermittent motion, and no frictional governor hitherto used can be depended on to produce perfect regularity. A second difficulty arises from the fact that no electro-magnetic effect is absolutely instantaneous, and that especially the effects on soft-iron cores, such as are frequently used in recording apparatus, are extremely uncertain or variable, so that an electro-magnet cannot be depended on to release or attract an armature at constant intervals after a given current is stopped. No doubt if every circumstance attending every experiment could be maintained rigorously the same, the electro-magnet would act constantly in one way; but in practice this cannot be effected.

M. Gloesener proposes to overcome this difficulty by using the deflection of a light galvanometer needle to register the cessation of the current, considering that although a certain time is doubtless required to produce even the smallest deflection, nevertheless the time will with equal currents be a constant quantity.

Dr. W. Siemens has used the spark from a Leyden jar to mark a polished metal cylinder, and so dispensed with all electro-magnetic gear.

M. Hardy at the suggestion of M. Martin de Brettes has, with the same view, used the spark from an induction coil to mark a small hole in paper; inertia is thus avoided, and very little time lost; but unfortunately sparks move very capriciously, sometimes darting to the one side and sometimes to the other, instead of going always in one direction. They sometimes, therefore, make their mark apparently a little too soon, and sometimes a little too late. The description of the apparatus exhibited will show how much talent has been exercised in the design and execution of these instruments.

E. Hardy, Paris, M. (France, 1,393), exhibits a chronoscope of excellent workmanship, and admirably arranged in most respects. It registers by means of an induction spark produced in a secondary circuit, by the rupture of the primary, and may be divided into the following parts for facility of description. 1st. A fixed brass cylinder, one metre in circumference, round which a band of prepared paper can be firmly stretched. 2nd. An axial arm of steel bearing a platinum point which revolves, describing a circle concentric with, and close to the cylindrical surface of the paper; this arm is driven by clockwork. 3rd. A pendulum revolving round a prolongation of the axis of the cylinder and driven by the axial arm, which presses against the lower end of the rod. This pendulum is intended to produce uniformity in the movement of the clockwork. 4th. An induction coil with primary and secondary circuits; one end of the secondary circuit is in connection with the point of the axial arm, and the other with the large brass cylinder on which the paper is stretched. The primary circuit is connected with a screen used as a target in the manner just described, and a current is allowed to circulate through it. The rupture of the screen, by interrupting the primary current, determines a spark in the secondary wire, registering the instant of the interruption by burning a small hole in the paper. By the armatures of a series of electro-magnets, the primary circuit can be re-established through a succession of wires and screens, giving a series of observations. Each interruption of the primary circuit is said to last about $\frac{1}{50}$th of a second.

Extraordinary care has been bestowed on every detail of this instrument; the wheels of the clockwork have all helicoidal teeth; by which great smoothness of motion is obtained; even the bevel wheels transforming the horizontal motion of the driving barrel into the vertical motion required for the axis of the conical pendulum have teeth cut on this principle.

The cylinder on which the paper is stretched can slide down along the axis; this motion is intended to allow a succession of observations to be made without stopping the instrument. If the series of observations follow each other rapidly, the cylinder simply slides down for a few seconds, restrained in its motion by a fly; but an arrangement is also provided by which, if required, the fly is only freed for a very little while after each spark, and then again locked, so that the observations may be continued for hours. With this view the clockwork is provided with hour, minute, and second hands.

The heavy conical pendulum is gimballed on four points in one plane, allowing perfect liberty of oscillation. Adjustments are provided, by which the centre of suspension of the pendulum is made to coincide with the axis of the cylinder, and levels are attached to the instrument, by which the verticality of the central axis can be insured.

A little ivory tube on the point from which the spark is discharged prevents in great measure any deviation of the spark from a direction normal to the surface. The paper is prepared with a solution of ferrocyanide of potassium, which allows the spark to produce a very small well-defined puncture, instead of the usual ragged hole.

The pendulum is about sixty centimetres long, and the weight of the bob twelve kilogrammes. This pendulum and the axial arm make about forty-five turns per minute, and one millimetre on the paper consequently represents the 45,000th part of a minute, or the 7,500th part of a second. A fraction of a millimetre could be easily observed; but such observations would not give trustworthy results, inasmuch as the random deviations of the spark amount occasionally to one third of a millimetre in spite of the little ivory guard. It is observed that the spark is not produced at the very instant that the primary circuit is interrupted; but M. Hardy can measure the time lost from this cause by using the radial arm to break the primary circuit at a certain point of its revolution, and observing the angular distance which separates this point from the little hole made by the corresponding spark; the time lost in this way is found to be very small, and tolerably constant.

M. Hardy finds by careful experiment with an astronomical clock that he can depend on the perfect uniformity of the rotation of his axial arm. His experiments not only showed that the same number of revolutions were made in each minute, but that each revolution was accomplished at a sensibly uniform speed; at least, any error which may have occurred was less than the error due to the spark—*i.e.*, less than the 3,000th part of the circumference, or the 22,500th part of a second. There is no reason to doubt the truth of these experiments; but the uniformity of motion must have been due to M. Hardy's excellent workmanship, rather than to any regulation afforded by the conical pendulum. The slightest variation of driving power or resistance during any revolution, such as would be produced by a little want of truth in any of the train of wheels, or imperfect coincidence between the axis of the pendulum and the axis of the driving arm, would have caused the pendulum to travel in an elliptical path with an uniform motion of the radius vector producing want of uniformity in the axial arm. M. Hardy himself states that he observed this very effect when he used common spur or bevel wheels. The pendulum, therefore, could not have been the cause of the uniformity of motion during each revolution. Neither could it have determined the equality observed in the number of revolutions per minute, except inasmuch as it acted as an air vane, meeting with greater resistance as it deviated further from the axis. It is true that the period of a conical pendulum is the same as that of a reciprocating pendulum of equal length and weight, and that this period does not sensibly differ for small angles of deviation; but the simple effect of any increased driving power on a conical pendulum is to make it at once deviate beyond these very small angles, and assume the position corresponding to the speed at which the frictional resistance of the clockwork balances the accelerating force of the driving weight. During the change of position it is true that the driving weight has to lift the bob of the

pendulum, and during this time meets with greater resistance from this cause; but when once the pendulum has assumed its new position it offers no more resistance to the driving weight than it did in its old position, except such additional resistance as may be due to its more rapid motion through the air. In a word, except from this latter cause, the pendulum in one position gives the driving weight no more work to do than in any other, and can in no way act as a restraining break. A slight advantage is gained by its resistance to being lifted on an increase of speed, and by the acceleration which it tends to produce when falling towards the centre after any slight decrease in the driving force. It is believed that no existing governor produces a perfectly uniform movement of rotation.

The whole of M. Hardy's instrument exhibits admirable workmanship, and it is suitable to a very large number of researches, in which the accurate measurement of small intervals of time is required.

(To be continued.)

ELECTRO-MAGNETIC INDUCTION MACHINE.

WE have had an opportunity recently of witnessing in operation a very ingenious and valuable apparatus for obtaining from a few voltaic pairs, by means of magnetic induction, a continuous stream of electricity in one direction. The machine is entirely self-acting, and consists of two induction coils. The internal coils are formed of No. 12 copper wire, and the outer coils of No. 18 copper wire. The cores of the shools are 1¼ inch in diameter, made up of annealed rods $\frac{1}{16}$ inch in diameter. The break is rotatory, with two five-toothed break-wheels, and springs bearing upon them tipped with platinum; rotatory motion is given to the break by a ratchet-wheel, with upper and under reverse clicks. The commutator is reciprocating. It has two contact cores and four contact ports. The contact cores are carried by a crosshead attached to the central reciprocating rod and armature. The contact cores are insulated from the crosshead by means of glass tubes and gutta-percha washers. Each contact core has each of its ends divided into two portions, the outer portions have glass tubes cemented into them, and the other portions have the metal turned down to the level of the glass tubes. These contact cores move in the induction ports, and they alternately rest on their glass and metal portions; consequently, are alternately insulated from, and in contact with, each pair of ports. The battery at present used with this machine is a six-cell Daniell's, three cells of which are sufficient to drive it; zincs, 1½ inch by 8 inches. The break-wheels are so arranged that they make and break contact when the metal portions of the contact cores are full in the ports; consequently, in the best position for receiving the induced currents. These currents are carried off by means of helicle copper springs, which are attached to the contact cores at one end, and to binding screws at the other. The magnetism ceases in one set of spools just before it is excited in the other, and the consequent oppositely-flowing induced currents are caused to blend by the similar free poles of the spools being placed opposite; the remaining rectification of the induced currents is brought about by the commutator in the following manner:—Two of the induction ports are connected with each end of the combined induction coils diagonally, that is, the positive terminal is connected with the port nearest the spools on its own side, and with the one farthest from them on the opposite side; in like manner, the negative is connected with the nearest on its own side, and the farthest off on the opposite. From this it will be seen that when the two ends of the contact cores farthest from the spools are full in their ports, they will be in contact with the opposite ends of the induction circuit to what they will be when their ends nearest the spools are full in their ports, and that each oscillation will reverse these contacts; but at each oscillation the currents are reversed; consequently, one contact core will always receive a positive current, and the other a negative current. These machines can be made to give any degree of tension or quantity simply by varying the length and thickness of the wire with which the spools are wound, and may also be worked with one cell of a battery or more, as required; even the present machine, which is for large quantity, with slight alteration can be driven with one cell. The invention can be seen at the Whittington Club, Arundel-street, Strand, on application to J. B. Thompson, Esq., the patentee.

ON THE PATENT LAWS.

DISCUSSION.

(Continued from page 225.)

Mr. WM. HAWES said at present the discussion had gone entirely in one direction. Nearly every gentleman had, to a certain extent and in various degrees, supported the present system of patent laws, or rather the principles on which they were based. He would in the first place reply to the observations in the very able and modest paper of Mr. Webster, because that gentleman, while criticising severely the arguments contained in a paper which he (Mr. Hawes) read before the last Social Science Congress at Glasgow, he had done it in so agreeable a manner as to make it a pleasure rather to hear himself criticised than to raise a word of complaint as to the manner in which the freedom of criticism was exercised. They must allow him to say that he thought the paper they had just heard grappled with only a small portion of the subject. Mr. Webster treated the patent law as an inventors' law only. He did not touch the patent law as a public law, affecting public and national interests, but he had laid down the propositions that invention was entitled to protection, and that there was a property in inventions; and having stated these two propositions, he went on to defend them, and to show how that property should be protected and how that principle was to be supported. He (Mr. Hawes) would not gainsay that there was a property in invention, but he would say the patent law by which they attempted to maintain that property was injurious to the nation, was not on the whole beneficial to the inventor, and led a larger number into difficulty and ruin than to fortune and success. Mr. Webster had drawn a very interesting distinction between invention and discovery. It was a distinction which might be drawn in a paper of this kind, read before an intelligent body of men, but it did not apply to the great practice of the world. It was impossible by law to define the difference between invention and discovery, and so long as there was that undefinable difference there would always be great difficulty in practically separating them, and in maintaining that some of the greatest discoveries were not inventions; for what discovery did more good, or had saved more lives, than the discovery of chloroform? and yet the men who discovered that agent, by the rule now laid down, had no right to reward or to have their services acknowledged by the nation. He said it was taking a wrong view to endeavour to establish such a distinction. They could not maintain it in practice, and it would confuse instead of elucidate the question. It was a distinction without a practical difference, which he could not admit as applicable in this case. Reference had also been made to the protection afforded by copyright. He was told that the copyright protected one man only and one work only, whereas the patent right went beyond that, for it not only protected the inventor, but protected his machinery and property, and prohibited others from using that machinery and property without his leave and license. But a book, a picture, or any artistic work was only so far protected by copyright as to secure the individual producing it against the exact reproduction of that which he had produced, and the world was allowed to benefit by that work, and to use it as they pleased, improving upon it, using the same materials or arguments, so long as they did not copy or sell that which was an exact copy of another man's mind. There was protection to intellect and property in it; and when they went beyond that, and prevented men applying any portion of a previous invention without the leave and license of the patentee, they did an injury to society, they obstructed progress, they increased the cost of production to the public, and delayed rather than increased the progress of invention. These distinctions were worth bringing forward by the author; they were interesting, and deserved consideration; but they did not meet or grapple with the real question—What was a patent? what was it granted for? for whose benefit was it granted? and did it do good or harm materially? A patent right was a monopoly; it was a remnant of the laws of olden times. It gave a man a right for years, to the exclusion of all others. It prevented other men from using, by directly improving upon it, that which another had invented. It was originally intended, no doubt, for the benefit of the individual, and not for the benefit of the country, for the registration of specifications was originally intended to prevent the loss of inventions, or the means whereby new things were produced. He disputed the principle on which patents were founded. He repeated that it was for the benefit of the individual that certain restrictions were enforced, and not for that of the country. For instance, the registration of the specification was considered to be for the benefit of the patentee as well as of the public, and as the best means of perpetuating the discovery. The principle on which that registration was founded was not applicable to the present time. Every patent law was a prohibition to the world. When a specification was taken out, it was not, he apprehended, with a view of concealing the object, but rather of announcing the discovery to the world. It was a publication of what had been done, but which the inventor's own countrymen could not use without his license, though the rest of the world might use it without any charge whatever. His friend next him (Mr. Graham) reminded him that the patent might be taken out abroad. They might take it out in many countries, but what check was there against the use of it compared with that in our own? Some few patents were secured abroad, but with the great mass very little good was done to those who invested their money in foreign patents. The evil of the publication of specifications in the present

time was that it was the means of assisting our rivals abroad gratuitously to that for which we obliged our own countrymen to pay a royalty, so that while we sent them our inventions broadcast over the world to be used in other countries by our rivals, without payment, we taxed our own industry. Was that just to ourselves, and was it the means by which the patent law upheld the great manufactures of this country, and rewarded inventors? He said not only was the patent law injurious, but it was also detrimental to the progress of our own manufacturers, because it held out a premium to the manufacturers abroad to reproduce our best productions. Look at it in another point of view. What was the number of patents taken out annually in this country? There were about 3,000 new inventions patented per annum; this had gone on year by year since 1852, so that between 25,000 and 30,00 patents had been granted during the last ten years. Where, then, was the progress of discovery by which they could mark the beneficial effect of these 25,000 or 30,000 patents? What was the cost of them? A million of money had been paid in official fees. How much more would have been paid in law to protect them, if each had had to be defended in 150 Chancery suits, might be more easily imagined than correctly stated. There could be no doubt litigation was a matter which added considerably to the charges for those patents. Then how did they test the results obtained from these 30,000 patents during the last ten years? If they looked to the Jurors' Reports of the Exhibition of 1862—not the opinion of one or two of them merely, but of nearly all—they would see the opinion expressed that the results of new invention in the previous ten years were not such as might have been anticipated, notwithstanding the large number of new patents taken out. That was the result of a million of money spent on patents; that was the result of investments, many times greater, in the experiments, labour, and machinery required to justify taking out a patent, and in law expenses to defend them. Then, to go a little further, let them look at the amount of property in these patents. He had said on an average there were 3,000 patents taken out annually. There were 3,200 patents taken out in 1862. Of these 3,2000, 1,200 died a natural death before having arrived at the great seal, £5 in fees, besides other expenses being paid on each. That was the first instalment under this law—1,200 out of the 3,200 were not considered worth the £20 to secure the first step. The expenditure on these 1,200 was all lost. That left them 2,000 yet to be dealt with. Of that number only about 550 paid the £25 necessary to get an extension for three years; therefore there were about 1,500 of the 2,000, every one of which was impeding progress, and was a fetter upon some other genuine inventor; 1,500 sank and died rather than pay the £25 to continue the protection for three years. Then what became of the other 550? £50 must be paid at the end of the third year to continue the protection for seven years, and only 100 got to that stage, so that out of the whole 3,200 patents the full fees were only paid upon 100 for the extension of the exclusive right for another seven years. If they wanted stronger facts than those to prove the absurdity of the Patent Law, they had only to look at the records of the Patent Office to satisfy themselves that whatever of good there might be in the principle of patents, it was not to be found in the patent law as it existed in this country; but having these facts, what could be said in support of protection to property in patents, if only 100 out of 3,200 were worth £100 at the end of two years. We might be told that the argument he had used, that they were beneficial to foreigners while useless to ourselves, was of little value, because inventors might take out patents for foreign countries. That appeared at first sight an answer to the argument, and he was asked by Mr. Webster to show them an instance in which an invention of this country had been used to our disadvantage abroad. How could his friend expect him to show an instance of that kind? All he could say was if the patents were so useless to foreigners that they rarely or never used them, when they had no fees or law expenses to pay, when they could get them without labour, without anxiety, without taxation—if they were useless to them what use could they be to this country? If these patents were of so little value that they might be thrown broadcast among our great manufacturing rivals all over the world, could they believe the maintenance of the law under which they existed, and which involved taxation of the public to a great extent, and which pretended to foster invention and reward the inventor—could they believe it was of much service to this country? Let them look at the reward it gave to inventors—how was it tested, where to be found? Every speaker had referred to the losses which inventors encountered. It was notorious that the great bulk of inventions had not rewarded the men who had produced them. Undoubtedly men had been rewarded who improved upon the inventions of others. The men who invented the beautiful dyes from a waste and almost noxious product—the two distinguished men who discovered the existence of those dyes, never received a penny for their services; while a comparatively obscure chemist—a man having no right whatever to claim reward for the invention—took out a patent founded upon the skill and research of Faraday and Hofmann, and that man and others were making large fortunes from the results of the labours of those two great philosophers. He said, as against the country, that right ought not to have been granted. Then Smith, the inventor of the screw propeller, was not adequately rewarded; others had benefited largely by additions made to that great discovery, but the man who devoted his life to the subject got nothing for his patent. There were plenty of patents, extending over a long range of inventions, which had not been profitable to the patentees, which had, on the contrary, ruined the inventors, whilst the rewards had been reaped by a class of men who did not deserve the name of inventors, who would succeed whether they had patent laws or not; but who, out of a bad protective system, had derived large fortunes, and therefore were the supporters of these laws. The same language might be used with regard to the great originator of the Penny Postage; and the corn laws were at one time regarded as necessary for the protection of the interests of the British farmer; but he would say that the abrogation of the patent laws, instead of defeating invention, would be a great stimulus to it, and they would never, under the present law, do so much for this country or for individuals as they would by allowing every man to win the laurels earned by his own brain, and allowing the country to reward him for his labours. They did not find that the philosophers, the physicians, the surgeons, or the great artists and authors of this country were deterred in their career of usefulness or of invention by want of patents; yet they were not wanting in discovery, which they applied to the benefit of mankind at large. No country possessed greater philosophers, greater physicians, greater surgeons, or greater artists than this, from Sir Humphrey Davy down to Faraday and Hofmann, and yet all had worked on without the stimulus of the patent law. This was his view of the patent law; but while he was entirely opposed to the present law, he did not say there should not be some system by which real inventions such as those of Rowland Hill, Smith, Hofmann, and James Watt, should meet with some reward. He believed there were means to be discovered by which great inventors and great inventions—he did not mean mere additions and changes bit by bit, which he did not call inventions—might meet with a suitable reward. Means might be found by which great inventors—men whose genius led them *con amore* to pursue researches for the benefit of mankind—might be honoured as well as rewarded, and to that extent he desired to reward invention and the individual talent which had led to invention. He would in a few words just call attention to the extraordinary arguments that were used in support of the views that were brought forward by various speakers. They were told that the best mode of remedying these abuses was to have a committee of experts, to whom all inventions were to be submitted, by whom it should be determined whether a patent should be granted or not. Would a man who knew anything about inventions submit to have his plans tested by those who were in arrear of him? because the essence of invention—the position a man placed himself in as an inventor—implied that he had more knowledge than his neighbours, and was in advance of the experts to whom it was proposed to submit his invention; and, taking mankind as it was, a man who was an inventor, and was in possession of a new principle, would be unwilling to submit it first to such a body of men, and then be found to give up his idea because those men said it was not new, or it was not likely to be a profitable patent. An inventor must be a man in advance of his age, and yet he was to be asked to submit his plans to those who were behind him, and who perhaps could not thoroughly estimate the value of the new principle brought before them. Let them imagine Mr. Winsor, the inventor of gas-lighting, submitting his plans to those who would have been the experts upon public lighting in that day—the great oil-merchants—and asking them to decide whether gas was capable of giving as much light as the old oil-lamps. Did they think they would ever have had gas? In 1814 the idea was ridiculed of passing gas along the streets in pipes like water. Then, again, the idea of submitting to such a body the question whether a wheel should have twenty instead of thirty cogs, or a particular fix of gearing—it was nonsense to call that invention; or whether a lever should be ten inches long instead of sixteen? or whether a sewing-machine should have one shape of needle instead of another, or this or that kind of stitch?—to call those inventions was an absurdity and an abuse of terms. Patent right, if he understood it rightly, was to protect that which was entirely new and useful—not to protect those things which were the necessary consequence of the application of a man's ingenuity with hundreds working at the same thing day by day. There was one remark of his friend (Mr. Graham) he must notice, that was with respect to the reluctance of great manufacturers to encourage new inventions in their own branch of trade, and he illustrated his view by one case in which the inventor brought his own designs into operation, and made a large fortune thereby. His friend also said that very rich men never troubled themselves about new inventions; but he would say if there was one man in the metropolis more ready than another to advance capital in the promotion of a really good invention, that man was his friend Mr. Graham, and he thought that was the best answer to his friend's argument. The inventor must have a capitalist with him, because it was said not to be in the nature of things for an inventor to be rich. Many great inventors were comparatively poor men. Roberts, the inventor of the self-acting mule was a poor man; and probably a few days hence this room would be appropriated to a meeting for the purpose of providing a subscription for his daughter, who was left in bad circumstances. His principle was if there were inventors—if they acknowledged them as such, they ought to find some means by which their talents should be acknowledged by a grateful country; but he did not apply that observation to a host of men who had no right to the protection which they sought, and he denounced the present system as untenable upon any sound principle.

Mr. Newton Wilson expressed a hope that as there were many gentlemen present who were desirous of speaking on this subject, the Council would consent to the discussion being resumed on a future evening, and he therefore moved that the discussion be adjourned.

Mr. SPENCER thought there was a great mistake in the nature of this discussion. They were going into details, and no one looked at the great principle at stake. Sir William Armstrong, the *Times* newspaper, and all who advocated the abolition of the patent laws, went into matters of detail, which, when investigated, came to this, that the patent laws were not carried out as they ought to be; that patents which ought to cost only £5 cost £100; and that the large sums annually expended on that account were owing to so-called inventors being allowed to protect their inventions. He thought that was wholly beside the question. He thought, with all deference to Mr. Hawes, that he entirely misapprehended the question. He did not think they could judge from facts, for facts had been wrongly applied, because wrongly brought about. If they had an institution so badly conducted as to check invention rather than encourage it, and from thence it was argued that the patent law was wrong, he thought that was no argument whatever. He (Mr. Spencer) considered there was a right in the individual as well as in the public? There was an undoubted property in invention. Mr. Hawes said he appreciated the inventor, but could not appreciate the man who went on step after step in the improvement of an invention. He would refer that gentleman to his own case of James Watt, and he asked where would have been the splendid results now realised in our great commercial steam marine if there had been no improvements made upon Watt's discovery and invention? Were they to keep the ashes of the dead for hundreds of years, and say that no benefit should accrue to the man who brought the results of improvements before the public? What was the test of the value of an invention? It was the benefit the public got from it. If they could now get the same amount of horse-power from an engine with 3 lbs. of coal that Watt got with 8 lbs., he thought that was a *bona fide* advance, the merit of which was due to later invention. But that was attained step by step, and yet this was what Mr. Hawes had depreciated. He thought in the matter of property in an invention there could be no misunderstanding. A man having a small cottage was as much protected in his rights as the man with large estates. He said if a copyright was allowed, and if a man was allowed to print his thoughts, and give them to the public as his own, the man who invented ought to be allowed to do the same: and of the degree of merit in invention he did not think they were fair judges. If such a board as Mr. Webster had suggested had existed, nineteen-twentieths of the present patents would not have come into existence. He was not arguing so much upon the present state of the patent laws as the state they might be in if the suggestions of Mr. Webster and others were carried out. That was the question now before them. It was the question whether individual right was to be respected—whether a man had a right to hold his own invention as a property. If not, what was the use of discussing the matter? He held that on every ground there was a right. The man who invented had a property-right in the thoughts he had worked out into a practical form, and unless that right were accorded, invention would go down. They were arguing as if capitalists were the most liberal and appreciative class of men—as if their language was, "Come to me with your invention, and I will pay you handsomely for it;" whereas he believed the rule was (though there were noble exceptions), "I will get as much as I can for myself, and will pay as little as possible for it." So far, therefore, from holding the views of Mr. Hawes, that invention would go on better, he believed it would not go on at all. He spoke as a patentee himself—one of the step-by-step men. He had spent his life in doing certain things, and he believed he had done good in a small way; and if inventors did not look for money reward, they looked for large results in another way. But it was the case with some men that the genius of invention, was within them, and it must come out; and when it came out they were justified in keeping it to themselves up to a certain point. If they admitted that a man's thoughts were beneficial to the public, he had a right to the same protection, that he might receive the value of them in return, as he would receive in the case of his cottage or his houses and lands.

(*To be continued.*)

ROYAL SOCIETY SOIREE.

MAJOR-GENERAL SABINE's last reception this season was held on Saturday last at Burlington House, and, as usual, passed off with the most complete success, both Science and Art—for once associated to their mutual advantage, in spite of "Y.'s" pungent and too true letter to the *Times*—being called upon to do duty for the general entertainment.

Most noteworthy among the philosophical instruments dealing with electricity, both on account of its novelty and the beauty and variety of the phenomena produced by it, must be mentioned an apparatus for showing the rotation of an induction spark *in vacuo* when connected with an electro-magnet exhibited by Mr. Edward Atkinson, who has just received it from the celebrated Ruhmkorff. The apparatus consists of a powerful electro-magnet, mounted horizontally on a stand, to which is attached a bell-shaped glass receiver, closed at the end with a glass plate. A thick bar of iron, forming the pole of the electro-magnet, projects into the receiver, which communicates with a stop-cock screwed into the other extremity of the iron bar by means of a hole drilled through it. A vacuum can thus be obtained in the receiver by means of an air-pump. A ring of copper wire surrounds the pole of the electro-magnet at a distance of about two inches from it, and can be connected with one of the rheophores of an induction coil, the other end of the coil being in contact with the iron bar. A commutator is attached to the helix of the electro-magnet, for the purpose of making and breaking contact with the battery or reversing the current. When the receiver is exhausted, a spark passes between the pole of the magnet and the copper ring, and, if the iron bar from the negative terminal of the coil, it becomes beautifully illuminated by a violet light, which is seen on the copper wire when the induced current is reversed. If the battery be now connected with the electro-magnet, the spark is seen to rotate round the iron pole; and, on reversing the current in the magnet, it rotates in the contrary direction. The velocity of the rotation depends on the degree of pressure in the receiver, and the power of the electro-magnet. When the vacuum is tolerably perfect, a moderate battery power is sufficient to produce a rapid rotation; but, on admitting a little air into the receiver, the velocity is less, and it is necessary to increase the number of battery-cells in order to obtain the same rate of speed. The experiment is one of the most interesting in electrical science, and when a little ether vapour is present in the receiver, the effects produced are extremely striking.

Mr. Ladd exhibited a similar instrument (in which, however, the magnet did not form one of the electrodes), and a series of Geissler's tubes of unrivalled beauty.

But electricity was at work in other ways. Messrs. Silver & Co. exhibited one of the semaphores of the Patent Electric Signal Company, and there were relays, improved voltaic batteries, telegraphic insulators, and specimens of cables to which we cannot allude more closely. We must not forget to mention also the newly-imported gum, named Balata, a portion of which, in its manufactured state, was exhibited.

An electric safety distance-signal for railways, invented by M. Hipp, of Neufchatel, and in operation on many, if, indeed, not all of the Swiss railways, and, of course, on the London, Chatham, and Dover Railway, was examined with much interest. The signal consists of a column surmounted by a disc, which is turned edgeways to the line for safety, or flatways for danger. The disc is turned by means of a descending weight. The mechanism on which the weight acts is stopped by an electro-magnetic detent, connected by conducting-wires with a battery at the station. When the detent is set free, the signal is turned to its required position by the weight coming into play, and on reaching it signals back that it has done so. Ingenious contrivances guard against any impediment to the working or action of atmospheric electricity. Professor J. Clerk Maxwell exhibited an experiment to determine whether the earth's motion affects the refraction of light, a model of a body moving similarly to a particle of a fluid medium which rotates the plane of polarized light, and an opthalmoscope on an entirely new model.

The opthalmoscope exhibited by Professor Maxwell is founded on the principle of Helmholt's opthalmoscope, in which light is reflected into the patient's eye by a set of plates of transparent glass, while the observer looks into the eye from behind the glass plates. The chief difficulties in observing the structure of the interior of the living eye arise from the smallness of the pupil, which compels us to observe by looking in the same direction in which the light entered, and the refraction of light within the eye, which renders the image indistinct, unless we have the means of altering the convergence of the rays. These difficulties are overcome by a combination of two lenses of two inches focal length, forming a kind of inverting telescope which does not magnify. The eye of the patient is placed at an eye-hole two inches from the lens, and the observer places his eye at another eye-hole two inches beyond the other lens. Whatever may be the distance between the lenses, the two eye-holes are *conjugate foci*—that is, any ray passing through the one will pass through the other; so that, by placing the eyes as described, each person receives through his pupil any ray which emerges from the pupil of the other person. But, as the eye is not self-luminous, the light is thrown into the patient's eye by means of one or more thin plates of transparent glass, interposed between his eye and the nearest lens, and inclined at an angle of 45° to the axis of the instrument. The patient then sees distinctly the reflection of the lamp, candle, or aperture in the shutter of the window placed on one side of the instrument, while the observer, by looking through the other eye-hole, receives the light which emerges from the eye and passes through the transparent plates. By adjusting the distance between the lenses, the image of the lamp on the fundus of the eye is distinctly seen; and, if the patient looks to the side of the lamp next his nose, the entrance of the optic nerve, with its blood-vessels, can be seen, and the focus may then be more carefully adjusted so as to see the more minute structure of the parts. The light reflected from the cornea is seen as a diffuse disc of light, and does not greatly disturb the observation; but it is easy, by means of a wire passing through the tube near the observer's eye-hole, to cover the image of this spot without interfering with vision. The fundus of the eye, with the images of luminous objects on it, is then distinctly seen free from extraneous light. As the instrument is symmetrical with respect to the observer and patient himself, the size of the images being equal in the two eyes.

A new aneroid barometer, invented by Mr. Browning, without springs or chain, in which the indication is multiplied by the reflection of a ray of light, must also be mentioned. In appearance it somewhat resembles a balance such as chemists employ for quantitative analysis, being in a glass case on levelling screws. The principal lever which transmits the motion

from the vacuum chamber, is formed of a hollow square aluminium tube. The whole of the pivots work in jewels, and the bearings are of hardened steel working on aluminium bronze. The indications are read off from a pointer, showing a range of about three inches for one inch of the mercurial barometer. This ray of light can also be used to make the barometer self-registering, by means of photography.

Foremost among the spectroscopes was Mr. Gassiot's Kew instrument, which has been recently furnished with a train of eleven bisulphide of carbon prisms by Mr. Browning, who has introduced many improvements worthy of the highest praise. In the first place, Mr. Browning, taking advantage of the difference between the refractive and dispersive properties of crown glass and bisulphide of carbon, has substituted a prism of crown glass, having a refracting angle of 6° for one of the outer plates of each prism; the base of this crown glass prism being brought to correspond with the apex of the fluid prism. By this means the angle of minimum deviation of the prisms is so much, decreased that eleven of them thus constructed can be used in a circle instead of eight. An increase of dispersive power, due to refracting angles of 150° of the bisulphide of carbon, is thus gained, minus only the small amount of dispersion counteracted, owing to the dispersive power of the crown glass prisms being employed in the contrary direction. Again:—In the fluid prisms of the ordinary construction the sides are cemented on with a mixture of glue and honey. This cement, on hardening, warps the sides and confusion of the spectral lines is the result. To obviate this Mr. Browning attaches an additional pair of parallel sides to the prisms, a thin film of castor-oil being interposed between the surfaces. The outer plates are then secured by means of sealing-wax, or some cement at the corners. In the Kew instrument Mr. Browning has dispensed with this attachment at the corners, which is likely to prove prejudicial, and has secured the second sides in their proper position by extremely light metal frames which clasp the plates only on their edges. Thus arranged, they exert no pressure on the surfaces of the plates; they are quite out of the field of view, and can be handled without any fear of derangement. Each prism, in addition to this metal frame, has a separate stand, furnished with adjusting screws for obtaining proved horizontality of the prisms, and securing them at the angle of minimum deviation for any particular ray. By this arrangement the prisms can be removed and replaced without being touched—a matter of some importance, as all fluid prisms show different results with every change of temperature.

Applied science was well represented. We may briefly chronicle Gisborne's patent mechanical signal apparatus for naval use, as fitted on board Her Majesty's iron frigate Achilles, and his apparatus for striking large bells, whereby full tones are produced without danger of cracking the metal—exhibited by Messrs. Silver & Co. and F. N. Gisborne; a model of floating dock constructed for the Spanish Government at Cartagena; models of double-screw gun-boats, contributed by Messrs. Rennie; model of jointed cast-iron bridge, lighter than the usual form of wrought-iron girder, with diagram showing the strains, by Mr. Fleeming Jenkin; and specimens of cold-drawn steel tubes and gun-barrels, exhibited by Messrs. Harding & Hawksworth. These tubes were produced by cold drawing from a hollow ingot of metal in the same manner as wire is drawn, except as regards the difference in the tools required to produce the tubular form. As the power necessary is of course much greater than in drawing brass or copper, hydraulic pressure is employed. The hollow ingot of metal, fixed to a flange attached to the ram of the hydraulic press, is dragged through a collar or die placed on another flange cast on the cylinder. As the ram is driven forwards by the water it carries the tube or tubes with it. Tubes so drawn acquire a considerable amount of additional strength, for it is calculated that metal drawn into wire—say a piano wire—gains 300 per cent. of tensile strength, which is rather increased in this process, from the fact of the metal being acted upon both internally and externally, and thus a tube can be formed which is stronger even than the solid mass. Tubes or solid bars of metal of all sections appear to be produced with the greatest truth and regularity, and are of infinite application. Tubes can be made as small as a needle, or as large as an Armstrong gun, offering new facilities to engineers and artillerists. They seem to be admirably fitted for boiler-tubes, gun-barrels, piston-rods, heavy ordnance, and for any articles of similar form requiring precision, strength, and lightness. If steel tubes can be obtained as thin and as strong as appears to be possible by this mode of manufacture, a new field is opened to engineers, and new combinations may be formed, the limits of which it would be difficult to fix, especially in its relation to the steam-engine. Among the specimens exhibited were some steel tubes, which illustrated, possibly, the way in which the molecules of metal arrange themselves under great pressure, as on the surface of the tube a herring-bone damask was visible, the ribs of which, crossing along the axial line, descended on each side in regular diagonal stripes, about an eighth of an inch apart.

Messrs. Elliott exhibited some of Richard's steam indicators, which are now in extensive use. The peculiarity of them is that the piston has only a throw of seven-eighths of an inch, which is multiplied four times by a parallel motion. By this means diagrams can be taken with the greatest accuracy from engines with 250 revolutions per minute.

Here we draw to a close, although we have not yet exhausted the list of scientific objects exhibited. But Art was equally well cared for, the Queen being again among the exhibitors, and the new method of photo-sculpture being explained by its inventor, M. Willème, and by M. Claudet.—*Reader.*

CORRESPONDENCE.

BONELLI'S TELEGRAPH COMPANY.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—In your extract from London papers, headed "Challenge to the Bonelli Company," of the 30th ult., I perceive in one of the paragraphs a statement "That the system (Bonelli's) had been at work between Liverpool and Manchester since September last, without a single interruption from weather, or electrical causes." This is inaccurate, as the Bonelli line was entirely broken down from the middle of December of last year, to the latter end of February of the present one, during which time not a single message was sent or received between Manchester or Liverpool.

Yours truly, ———.

Manchester, May 11th, 1864.

A QUERY.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—I have constructed a bell; it works very rapid, but exceedingly weak; my battery consists on short circuit for experiment of six cells, with gutta-percha jars, and porous pots, and of copper 2½-in. × 7½-in., excited by very dilute acid (sulph.), sulphate of copper, and area of zinc plate, 2½-in. × 2½-in.

I want to connect seven rooms to one bell and indicators, and carry another to the workshop (75 yards length of conductor), and work them from one battery. Will twelve cells be enough?

If you, or any of your readers, will kindly favour me with the size wire for the magnet and dial, and length of the soft iron core, with the area of zinc and copper plates for a battery to work the above, I shall esteem it a great favour.—I remain, sir, yours respectfully,

AN AMATEUR.

TELEGRAPHIC NEWS.

SILVER'S INDIA RUBBER WORKS AND TELEGRAPH CABLE COMPANY (LIMITED.)—The Committee of the Stock Exchange have appointed the 18th instant for settling and marking the shares in the above Company.

SUBMARINE TELEGRAPH COMPANY.—The Tonning cable of this company, which had been injured by its having come in contact with a wreck, has been repaired under the superintendence of J. H. France, Esq., the acting engineer of the company.

LONDON DISTRICT TELEGRAPH COMPANY.—Telegrams can now be sent from any of the stations of the Metropolitan Railway to all parts of the United Kingdom and Continent at through rates. An arrangement has also just come into operation whereby messages for any of the South-Eastern stations can be sent from any of the London District Telegraph Company's offices at the same charges as from their own stations.

THE TELEGRAPH IN AMERICA.—The United States Telegraph Company have constructed during the past year nearly 2,000 miles of telegraph, and during the present season they intend to erect more than 4,000 miles more. Their lines are now in operation from New York to Albany, Buffalo, Cleveland, Chicago, and Milwaukee; and by way of Philadelphia to Pittsburg and Cleveland. Within a few weeks their lines will reach to Cincinnati, and during the summer will be extended to Louisville, Kentucky, and St. Louis.

INTERESTING TELEGRAPHIC FEAT.—Some telegrams sent on Monday and Tuesday from Heligoland by this line, narrating the progress of the naval action between the Austro-Prussian and Danish fleets, were received, owing to the difference of longitude, in the following order:—Sent from Heligoland at 12.23, received at 12.19; sent at 2.10, received at 1.49; sent at 4.15, received at 3.54; sent at 12.10, received at 11.50; sent at 12.23, received at 12.19.

ATLANTIC TELEGRAPH COMPANY.—We have been informed that the above company's cable is being now manufactured at the rate of ten miles per day. There is, however—as has been the case with all previous cables, with the exception of the Persian Gulf cable—the profoundest secrecy maintained with respect to the nature and extent of the tests to which it is subjected. A few weeks since a number of gentlemen were invited to witness the manufacture of the cable, but we looked in vain for the name of any one who could have formed any opinion on the subject as a practical man.

A SUBMARINE VESSEL.—Several of the Continental journals contain the following paragraph:—"A submarine vessel of colossal dimensions is now being built at Cronstadt, in the construction of which 2,000 tons of iron and steel will be used. She is to be moved by two large engines, worked by compressed air, is to be armed with a powerful spur, and will carry every accessory for fixing to the hulls of vessels large cylinders of powder to be fired by electricity. Large glass-covered openings will enable the crew to direct the course of the vessel; they will also be able to regulate the depth at which she is to swim, but in general the vessel will be near the surface. The Emperor recently signed a decree appropriating 673,000f. for the construction of the sea monster."

The United Kingdom Telegraph Company.—The above Company have now extended their wires to the important towns of Cardiff, Newport, and Gloucester, at which stations have been opened for public business; the charge being 1s. for each message of twenty words.

Telegraphy in Vancouver's Island.—The *Weekly British Colonist*, of the 15th March last, states that on the previous Saturday his Excellency the Governor gave his assent to the telegraph bill lately passed through both houses, and it is now the law of the land. It is to be hoped that the construction of the telegraph line will be commenced and carried on with a like commendable despatch, and that we may before the close of the present year be enabled to exchange greetings with our eastern neighbours, and perhaps even with the old folks at home.

Cape Clear Telegraph Station.—The British and Irish Magnetic Telegraph Company have stationed a steamer at Cape Clear to intercept the American Mail steamers, and thus expedite the transmission of messages from that point. In order that messages may be placed in the company's canister for Cape Clear, merchants and others receiving messages from America should instruct their agents to have the messages marked "viâ Cape Clear." Arrangements have also been made for reporting vessels passing Cape Clear for owners and consignees, and for placing orders on board.

Contract Messages.—The London District Telegraph Company, in order to facilitate the more general use of the telegraph, announce that it is prepared to enter into subscription contracts for any number of messages, at greatly reduced rates. The reduced scale under this arrangement will be 20s. per 100 messages, not exceeding fifteen words each (exclusive of name and address of sender and receiver), and for extra words at the same rate, exclusive of any special charge for porterage. The messages must be addressed either to or from the subscriber. It is required that each subscriber should take 20s. worth of free message franks to commence with; an account will then be opened on the above terms for future messages, and which will be forwarded from any of the Company's Offices without prepayment.

The Great Eastern.—A morning contemporary states:—"We are informed that the steamer Great Eastern has been sold to the French for a sum approaching a quarter of a million sterling. This, however, will not interfere with her present engagements, which include the submersion of the Atlantic cable. The Great Eastern was purchased at Liverpool, at auction, about three months ago, for a sum of £25,000, but, as the mortgage debentures had been previously bought up, the total cost was, probably, £70,000 or £80,000. There is, however, a very handsome profit on the present transaction. At the time of the excitement in connection with the Trent affair this vessel took out a very large number of English troops to Canada at a single trip; and in view of her great capabilities for this and similar services, her present transfer altogether from English hands is regarded with regret in some quarters. It is rumoured that the purchase has been made on account of the French government."

The subjoined is a copy of a letter posted at Lloyd's to-day. The writer, Captain Rowett, has lately obtained from France a concession, giving him exclusive right, for 50 years, to lay telegraph cables from that country to America:—"32, Charing-cross, May 9.—Dear Sir,—The time has arrived when the committee you have the honour to represent can do their part in adding another insurable difficulty to the vast field of operations already known to underwriters. By the concession lately granted you will have seen that the great cause of ocean telegraphy has been taken under the patronage of the Imperial Government of France, and there can be no doubt more than a hundred millions sterling of insurable risks will be developed. To this end I am prepared to prove to underwriters—1. That there is no moving water at the bottom of the ocean. 2. There is no pressure at the greatest depths to injure any cable. 3. That the cable will rest at the bottom without risk to its electrical integrity. 4. That a hempen cable, with the properly-insulated conductor in its centre, can be laid safely, and be under perfect control in stormy weather as well as in fine. 5. That when a good hemp cable is not loaded with iron it can be recovered even from the greatest depths as certainly as the hempen sounding line has so often brought up with it specimens of the bottom. 6. That hemp absorbs and holds a solution which preserves it from decay, which iron cannot do, but is subject to destructive corrosion by the salt, which on the other hand, is well known to preserve hemp. These facts alone render ocean telegraph cables simple and insurable risks at moderate rates of premium, when coupled with the proper electrical tests after it has been shipped. But I am prepared also to show that currents of the ocean do not exist but in a superficial degree; and are in no way dangerous to the laying of ocean cables. Permit me to remind you that it was officially reported the current had carried away the Atlantic cable, in fact, that the necessary restraint of 35 cwt. on the breaks broke it, and thus nearly 400 miles of cable was lost. What can be more dangerous than to act under erroneous impressions? The fact is, in extreme depths the weight of the iron cable was so great that it could not be controlled, and it broke from this cause. Current had nothing whatever to do with it. By this and similar errors in the present practice of ocean telegraphy the country has been for years deprived of a vast industry for the labourer, besides the commercial, social, and imperial advantages, which are incalculable. I shall be glad to explain this subject to any of your underwriters, and I have the honour to remain, your obedient servant, W. Rowett.—Capt. G. A. Halsted, R.N., Lloyd's, Royal Exchange.

The Atlantic Telegraph.—The cable destined to connect America with Europe has now been fairly commenced, and by this time next year we expect to announce the preparation for, if not the actual departure of the Great Eastern steamship with the cable on board. It is understood that neither Her Majesty's Government, nor that of the United States, will again grant the use of any of their vessels, as on the occasion of the former attempt; the Company, therefore, will have to rely entirely upon their own resources. On the former occasion the cable was carried in two ships, and the difficulty of laying it was, of course, considerably increased by the fact of each ship having to lay its own portion practically independent of the other. The Great Eastern will admit of the whole length of the cable being stowed away on board, and in such a manner as to be payed out with much greater facility and less risk of failure than from the hold of the smaller frigates formerly engaged. The "big ship" will also, there is every reason to believe, pitch much less than a smaller vessel, and consequently cause less strain upon the cable in the process of paying out, with a corresponding diminution in the risk of damage. Not only are the prospects of successful submergence greater than before, but there is every reason to believe that the cable, when laid, will satisfy all the electrical conditions necessary for its success.

The United Kingdom Electric Telegraph Company.—On Monday, this company opened their offices in Edinburgh and Leith, so that "shilling telegrams" may now be dispatched from Edinburgh to London, Liverpool, Manchester, Birmingham, and all the leading towns to which this company has opened communications. This is the first Scottish line of this company, and it runs through Dalkeith, Jedburgh, &c., to Newcastle, where it joins with the company's other trunk lines. The Shilling Telegraph Company use the printing instrument and relay system of Messrs. Siemens & Halske, by which all large towns are put in direct communication with each other by a kind of automatic manipulator, so that the company have not only brought us a boon of a "shilling telegram" system, but also a kind of guarantee for efficient and quick working. This company has also obtained the exclusive right to use Professor Hughes' type-printing instrument, which prints the message in actual Roman type; and the company are making great preparations for extending the use of this instrument. By means of this instrument a single wave of electricity gives a complete letter, and at such an excessive speed that the fastest writer cannot keep up to it. The company's main trunk lines already open are from London to Liverpool, through Oxford, Leamington, Birmingham, Wolverhampton, Manchester, &c.; also from London, through Uxbridge, Nottingham, Sheffield, Wakefield, Leeds, Sunderland, Hartlepool, Newcastle, and Edinburgh, to Glasgow. Another trunk line runs through the west of England, connecting nearly all the principal sea-ports. The company's offices are situated at No. 1, Hanover-street, Edinburgh, and in the Exchange-buildings, Constitution-street, Leith.

The Indo-European Telegraph.—It will be satisfactory to learn that the Persian Gulf cable has been landed at Fao, and that the difficult operation of carrying it over an almost impassable sea of mud to Busra, and uniting it with the land line at that place, has been successfully accomplished. The most perfect telegraphic communication now exists between Busra and Kurrachee, and Colonel Patrick Stewart will proceed to-day (the 12th inst.) in one of the government river steamers to Baghdad, conveying congratulatory messages from the Indian Government to the Secretary of State, on the successful submersion of the Persian Gulf cable. These messages will be transmitted from Baghdad by the Turkish and Mediterranean telegraphs to Europe in a few hours. Colonel Kemball, the political agent at Baghdad, is engaged, at the instance of the Turkish authorities, in negociating with the Arab tribes along the right bank of the Euphrates for the safe passage of the telegraph wire between Baghdad and Busra. His knowledge of the Arab character and long experience of the country will, it is anticipated, enable him to remove all difficulty to the extension of the wire along this tract. The telegraph works between the Turkish frontier and Persia are being vigorously prosecuted under the superintendence of Captain Champain, R.E. It is confidently reported that India will be in direct telegraphic communication with Europe, viâ Persia and Turkish Arabia, in the course of a few weeks.—*The Times of India.*

The Wonders of a Watch.—There are very few of the many who carry watches who ever think of the complexity of its delicate mechanism, or of the extraordinary and unceasing labour it performs, and how astonishingly well it bears up and does its duty under what would be considered very shabby treatment in almost any other machinery. There are many who think a watch ought to run and keep good time for years without even a drop of oil, who would not think of running a common piece of machinery a day without oiling, the wheels of which do but a fraction of the service. We were forcibly struck with this thought the other day, upon hearing a person remark that, by way of gratifying his curiosity, he had made a calculation of the revolutions which the wheels in a watch make in a day and a year. The result of this calculation is as suggestive as it is interesting. For example:—the main wheel makes 4 revolutions in 24 hours, or 1,460 in a year; the second or centre wheel, 24 revolutions in 24 hours, or 8,760 in a year; the third wheel, 192 in 24 hours, or 69,080 in a year; the fourth wheel (which carries the second-hand), 1,440 in 24 hours, or 525,600 in a year; the fifth or 'scape wheel, 12,960 in 24 hours, or 4,728,400 revolutions in a year; while the beats or vibrations made in 24 hours are 388,800, or 141,812,000 in a year.

MISCELLANEA.

TORPEDOES.—Is it impertinent to inquire if our government is good enough to direct any one's attention to "torpedoes?" We are serious. The United States sloop-of-war Housatonic has been blowed up and destroyed by one of these contrivances. The fine steam-frigate Minnesota has had a most narrow escape from utter destruction with all on board by similar agency. So it is a real, practical, and very terrible agency in war; and it is set at work by those poor Confederates, who have little to aid their ingenuity in mechanical appliances.—*American Paper.*

TELEGRAPH REGISTER.—In all telegraph registers heretofore constructed, the style or steel pen is so attached to the pen lever as to be immoveable laterally; and in order to write upon the paper in as many lines as practicable, the paper has to be moved laterally and the working surface of the rollers has to be of a length almost equal to twice the width of the paper. As one of the rollers is pressed upon the paper by means of springs bearing on each end of the roller, every time the paper is moved laterally these springs have to be re-adjusted, else the pressure of the roller will be greater on one edge of the paper than on the other, causing it to run untrue in its passage between the rollers. Mr. Robert Henning, of Ottawa, Illinois, U.S., thus describes an improvement on all other forms of telegraph registers:—The main object is to obviate the necessity of moving the paper laterally, and thereby obviate the above difficulty; and to this end it consists in the arrangement of the style or pen in a holder which is moveable in a direction parallel with the length of the rollers, by which means also the machine is enabled to be made much narrower, requiring less pinion wire for its construction, and the clock train is made to run more truly by reason of the axles being shorter. This moveable pen necessitates the provision of several grooves in the roller against which the pen operates, instead of only one groove as in the rollers of the registers heretofore constructed, the said grooves corresponding in number and in distance apart with the lines of writing desired to be made on the paper; and the invention further consists in a certain mode of combining the moveable pen-holder with the pen lever, and adjusting it relatively to the several grooves of the roller, whereby the said pen is enabled to be brought exactly opposite to the said grooves and the lines of writing on the paper are always made at equal distances apart, so that a greater number of lines are enabled to be made upon the paper, and the paper thereby economised.

COPPER.—The whole earth appears to be more or less impregnated with this beautiful and useful metal, and the sea contains a notable quantity of it. Copper is in great abundance in various parts of the British isles, in Hungary, in Siberia, in Cyprus, from which island it derives its name, and whence, no doubt, on account of the geographical position of that island, it was principally procured by the Romans. It is also found in China, in Australia, and in Brazil—in fact, almost everywhere. It appears, however, certain that gold and silver were known to the ancients prior to copper. According to Ezra viii. 27, "Copper was as precious as gold." Paul, in 2 Timothy iv. 14, lays a complaint against one Alexander, a coppersmith. These are the only instances in which mention is made of this metal in the Holy Scriptures. Copper takes a rank among metals from its peculiar colour, which, when pure, is of a rose-like hue. Most metals when they become rusty lose their beauty; not so, however, with copper, for it changes into various shades, from pink to a beautiful crimson, as in copper bronze powder, to blue, to green; hence the artist takes it as a pigment to produce upon his canvas "the fields and the forest." In the metallic state copper possesses so many useful qualities that various metal-workers find it of great service. It bears such "wear and tear" that it was adopted as money at a very early period, and retains its good name to the present time. Copper is one of the best conductors of lightning; hence it will be employed to transmit "the flash" below the restless Atlantic, in forming the submarine telegraph between England and America. This metal is so sonorous that few musical instruments can be made without it. The Handel organ and "Big Ben" of Westminster alike owe their tone to copper. Musicians, electricians, artists, and money-makers are not the only persons whose "occupation would be gone" were it not for copper. Colour-makers and dyers are much indebted to it, as well as a host of others who follow the same trade as "Alexander the coppersmith."—*Piesse's Laboratory of Chemical Wonders.*

THE ELECTRIC WAVE.—Mr. Samuel B. Smith, in a communication to the *Scientific American*, says:—"The electric current runs just as a cylinder of two feet diameter runs when turned by a crank and pushed longitudinally at the same time. We turn from the left to the right. So rotates or turns also the electric current or wave—from the left to the right. This law, as it relates to the electric current, is universal. We see that the cylinder turns at its remote end simultaneously with its turning at the crank end. So, likewise, is the turning or revolving of the electric wave. In regard to the wave, however, if the line of its motion be extended to a great distance, the motion of the wave at its terminus is not *precisely* simultaneous with its motion at the commencement. This is owing to the obstacles it has to overcome in its long passage, owing to the imperfect conducting properties of the intervening media along which it has to pass. While the electric wave is thus rotating, it generates at its central line of motion a current at a right angle with its motion; and this is magnetism. This magnetic force or current does not rotate, but runs in a direct course from one of its poles to the other, in a line the motion of which commences with that of the electric wave. This magnetic force or current is very strikingly exemplified in the helices of the ordinary electro-magnetic machines, where the iron wire that is introduced into them becomes powerfully magnetic, with its north and south pole. Besides this rotary motion, the electric wave has also a lineal motion; that is, it moves directly forward simultaneously with its rotation; this constitutes a spiral motion. There is something sublime in contemplating this wonderful force. In it there is found the epitome of the universe. Its rotary and lineal motions represent the motions of the heavenly bodies on their own axis, as well as their obitual motions; the one confined to its own centre, and the other rushing from it. Electricity in motion begets magnetism; and magnetism in motion begets electricity. The two elements, although so intimately related to each other, are, nevertheless, totally distinct in their powers. Glass offers an insurmountable obstacle to the transmission through it of electricity; while magnetism passes through without the least resistance. The passage of electricity is instantaneous, leaving no traces behind of its presence. Magnetism, on the contrary, on certain metals, such as steel, remains in full force. Electricity gives, but loses while it gives; but, wonderful as it may seem, magnetism gives and loses nothing. With one magnet we may make a thousand, without its losing the least of its magnetic power. It seems to be a God-like power. 'God,' as we read, 'created man in his own image.' Gen. i. 27. Yet God is the same he was before man was created, so the magnet remains the same after making other magnets. It is, doubtlessly, these two great principles that sustain the universe, and impart and regulate all its motions."

The *Telegraphic Journal* is the most effective medium for inventors, patentees, contractors, manufacturers of insulating materials and electrical apparatus to submit their various specialities to the consideration of secretaries and managers of telegraph or railway companies, and other persons engaged in electrical and telegraphic pursuits.

Clerks, assistants, manipulators, and instrument makers, seeking employment, &c., will find the *Telegraphic Journal* a ready means of making known their requirements.

DOMESTIC TELEGRAPHY.

It is said that every Englishman's house is his castle. His home may be called his microcosm. He loves to make it his little world in which he can disport all the fancies of his imaginative mind, and nurture the offspring of his fertile brain to minister to his wants and add to his comfort. How soon he applies to his domestic requirements the inventions and appliances of the outer world. He has subdued fire, steam, hot air, coal, &c. to warm his frame, prepare his food, dry his materials, protect him from cold in winter, and diminish the effects of heat in summer. Gas illumines his pathway and brightens up his hearth. Chemistry surrounds him in everything he eats and drinks. Natural philosophy confines him in secure materials, ventilates his rooms, reduces his labours, softens his toils. Electricity now steps forth—his humble but willing slave.

Its admirable adaptability for domestic purposes has recently been fully explained in these columns; and in again calling the attention of our readers to the new electric bell, we are fully impressed with the conviction that electricity has supplied a new want of the age. What householder has not cursed in his heart the bell-hanger. You have carefully laid down an exquisite Brussels carpet—your new furniture is all elegantly arranged—the walls are exquisitely decorated with the newest devices from that great centre of taste and show, Paris—when a sudden jerk at the pull ruptures the bell wire! The bell-hanger is sent for; up comes the carpet, down goes the furniture, and the anatomically correct impression of an oily human hand ornaments the paper.

You are lying ill in bed—sleep has been a stranger for hours—you are just dozing off, as the shades of evening are casting a gentle gloom over the room, in a quiet generous slumber, when a horrid grating noise startles you out of your senses and drives Morpheus away for several more hours. Paterfamilias seated in his cozy arm-chair wants another bottle of port, and his heavy hand on the awkward pull has strained the stiff wire and raised the dreadful *rumpus*. Electricity avoids all this. You have but to impress a slight touch upon a button—the electric force starts into play—it steals noiselessly along the wire, and produces a violent agitation of the "tintinabulum" which would arouse the seven sleepers, were they within hail.

Considerable hesitation has been shown in the introduction of this power into our houses, owing to the imagined trouble and difficulty in maintaining the battery in order. This is pure supposition. The battery will be found to require infinitely less trouble than the gas, water, or any other convenience in a modern establishment. An examination about once a month, an addition of materials about every three months, a cleansing every six months, and a renewal of materials every year are the worst contingencies, and what is this? We have brought the lightning down from heaven to run upon our errands, to bring intelligence over wilderness and under oceans from the uttermost ends of the earth. We guide the mariner through the dark and tortuous channels by its brilliant scintillations. We protect the lives of the millions of human beings that entrust their bodies in the whirling train by its power. And can we not spare one hour a month to domesticate that wonderful power, to comprehend its beautiful action, and to impress its simple principles into our daily service and hourly wants? Man has subdued more difficult agents than electricity to his domestic purposes, and he will soon add the tamed lightnings to his household gods. He has but to understand it, and he will mould it to his will in many useful and advantageous forms. He will use it not only to attract the attention of his servants, but to communicate his commands from floor to floor. He will have it between his hall and his stable, to bring up his carriages and order out his horses. He will, by its means, protect his property from the depredations of robbers. He will, in fact, make it a protector, a companion, and a slave.

THE CONSTRUCTION OF TELEGRAPHS.

In a recent number we laid before our readers some remarks upon the construction of a line of telegraph. In continuation of the subject, we now propose to take into consideration the battery and instruments—the method of charging the batteries and connecting them with the instruments at the various stations.

We have six wires at our disposal, and shall make use of them as follows:—

2 Double-needle Telegraph.
1 Printing.
3 Train-signals.

The first consideration will be the battery. There are many forms of battery, most of which claim our favourable notice. Our choice, however, lies with that of the Daniell form, or sulphate battery; it is constant in its action, requires but little attention, and is easily transported from place to place. Of these the most approved are, the "Muirhead," "ordinary sulphate," and "Fuller." With regard to the power requisite to work a circuit, much information may be obtained by studying the rules quoted and laid down by Mr. R. S. Culley, in his "Handbook of Practical Telegraphy," recently published. "The greatest effect of a given number of cells is produced when they are so arranged that the battery resistance equals that of the line;" but, as faults and leakage will at any time occur, it is advisable that the resistance of the battery should be considerably less than that of the line. When a fault arises, or wet weather prevails, the resistance of a circuit is diminished, in consequence of the means of escape afforded to the current by the fault, or from the dampness of the insulators or supports upon which the wires rest. On a short circuit, or badly insulated line, a quantity battery—that is, a battery formed of large-sized plates—may be used with advantage. On a long circuit, well insulated, there is, however, little if any advantage in increasing the size of the plates, but much may be gained up to a certain limit by increasing their number. The principal thing to bear in mind is, that there must be sufficient quantity to supply the leakage, and sufficient tension to drive a current to the distant end or terminal station. If not procurable a quantity battery can be made up by placing those of smaller plates side by side. Thus, instead of joining the copper terminal of the one to the zinc of the other, connect them up zinc

to zinc, and copper to copper. By this means, with two batteries we double the quantity. The tension will remain the same, but the resistance will be halved. It must, however, be borne in mind that there is a certain disadvantage in employing such a battery for any length of time, unless the cells are all equal in power and conductibility, which will certainly not remain the case for any lengthy period—the stronger will send a current back through the weaker. A deposit of copper forms on the zinc, completely destroying the electro-motive force. Consequently, it is much better to use batteries with plates of double the size—say of 32 square inches—rather than two plates of 16 square inches placed side by side.

We will suppose our wires to extend over 80 miles of line. The double-needle circuit is to accommodate five stations, into which the wires have been led. The printing circuit is to be provided with three instruments—two terminal, one intermediate—whilst the train-signals are made use of at huts erected one to every five miles of line.

Of course, were all circuits to be fitted up at once, the batteries, instruments, &c., for each station should be all sent off together in charge of a man in whom you can place reliance, to be deposited by him each at their respective station; but for convenience and clearness in explaining their different connections we prefer to take each circuit by itself.

The line wire is 80 miles in length, of No. 8 wire, and gives we will say a resistance of 40 miles. Each instrument will add 20, so that we may reckon the total resistance of the circuit as 140 miles. Four intensity batteries will be sufficient to work the circuit. Let them be got together and, with the instruments, labelled, and sent on to their respective stations. We must not forget to test each instrument before starting it. This is done by connecting up a battery to the two front terminals—zinc to Z and copper to Y—and joining the remaining two terminals, A B and C D, on either side together. The instrument is then on short circuit, and whatever signals are made by means of the handles should be recorded by the needles. Time is of importance at all times, but especially so on a railway, where the loss of a minute may, perhaps, detain you some hours. Consequently, if the batteries are supplied with their plates and sulphate of copper previous to their despatch, it may prove of advantage. Each copper cell should be supplied with about two ounces of sulphate of copper, sufficiently bruised to admit it with ease within the cell. If you require the battery for immediate use a little sulphate of zinc deposited in the zinc cells will quicken its action. A few drops of sulphuric acid will afford us like assistance.

The lineman who is to have charge of the length should be present when the instruments are joined up, that he may himself see all joints are well made and securely covered. It is manifestly to his own interest to look to all these things at the outset. Let him, therefore, accompany you. As we pass down the line, at each station where an instrument is to be put in circuit we hand out the necessary articles. Arrived at the distant or terminal station we set to work, and whilst one is looking to the batteries, filling each cell to within an inch of the top with water, the inspector may be joining up the instrument. The batteries should have provided for them a closet or other secure place, where they are not likely to be interfered with. At large stations it is usual to have a room devoted entirely to the batteries, where, arranged upon racks, each separate set is marked according to the circuit upon which it is employed. In joining them up we have simply to connect the zinc pole of the one to the copper of the other, leading the terminating wires of the whole set, zinc and copper, up to the instrument, connecting them to their respective terminals, usually copper to the right-hand front terminal (marked Y), and zinc to the left-hand (marked Z).

(To be contir

MAURITIUS ON THE INFLUENCE OF HEAT ON MAGNETISM.

Dr. Mauritius, of Marburg, has communicated to *Poggendorff's Annalen* the results of a series of experiments instituted by him with a view to determine the influence of heat on bar magnets. The subject has been previously investigated by Wiedemann (*Pogg. Annalen*, vol. c. p. 241, and ciii. p. 563); and it was partly to check the results obtained by him that Dr. Mauritius undertook the researches of which we are about to give a short account.

The first part is devoted to a description of the effects produced by alternately heating and cooling magnetized bars from 212° to 32°, and is little more than a repetition of the experiments of Wiedemann, to which we have previously referred, the results of which, however, are not on all points confirmed by Dr. Mauritius.

The second and more interesting part describes a series of experiments on temporary magnetism at very high temperatures—a subject which is touched upon by Barlow in his "Essay on Magnetic Attractions." The object which Dr. Mauritius had in view was to ascertain the coercive force of iron and steel of various qualities at elevated temperatures; and for this purpose he made use of the following arrangement of apparatus:—An ordinary electro-magnetic coil, 8½ inches in length, and consisting of five layers of copper wire of ·078 inch in diameter, was placed perpendicular to the magnetic meridian, and in the same horizontal plane with a delicately-poised magnet ·23 inches diameter and 2·3 inches long. This was suspended by a single thread, consisting of two fibres of silk about 3 feet in length, and was furnished with a mirror in the usual manner, the deflection being read off by means of a telescope, on a scale divided into millimètres, and situated at a distance of 3 feet 6 inches from the magnet.

The method of bringing the magnet to rest, after each observation, was ingenious, and is claimed by Dr. Mauritius as novel. At a suitable distance in front of the needle he placed a coil of copper wire, having its axis east and west, and through which, by means of a commutator of simple and, indeed, almost primitive construction, he sent a current in the direction necessary for checking the vibration of the magnet. By the use of this he was enabled to make sixteen separate observations in the short space of half-an-hour. The commutator was constructed by driving three nails into a board, so as to form an equilateral triangle, the nail at the apex being much larger than the other two, and driven through and clenched on the other side of the board. The large nail was also bent twice at right angles, so as to form a sort of handle, by which it might be brought into contact with either of the small nails at the base of the triangle. When left to itself, it hung freely between the two. The battery consisted of two pairs of plates excited with weak acid, the zinc pole of one pair, and the copper pole of the other, being each connected with one of the smaller nails. The two remaining plates were connected with each other, and also with the large nail. It will be apparent, from this description, that the current would be reversed by moving the large nail from one to the other of the small ones. By simply releasing it, the weight of the nail causes it to assume a position midway between the other two, and the circuit is broken.

The bars experimented upon were four in number, and were all about six inches in length, the first being of wrought iron, the second of English cast steel, and the third and fourth of cast iron. They were, first of all, heated to a white heat, and then placed carefully within the coil, contact with the battery having previously been made. Some time elapsed in all cases after the introduction of the bar into the coil, before any motion of the magnet took place, but the steel bar behaved in the most remarkable manner. For a short time it produced no effect upon the needle, but, when it had cooled down to a certain point, it suddenly became magnetic, the magnetism increasing gradually with the falling temperature. This increase went on for some time, until at length the needle again remained stationary for a short period, at the end of which the phenomenon of the sudden appearance of the magnetism was repeated, and the magnetism increased in quantity until it attained its maximum. The same irregularity occurred, to some extent, in all the bars experimented upon, but less in the cast than in the wrought iron.

It is apparent, therefore, from these results, that the coercive power does not decrease gradually with the fall in temperature, and that there is a point above which no magnetism is communicated to the iron. When the heat sinks to this limit, the

magnetism appears suddenly, and goes on increasing until we arrive at a second interval, during which the needle remains perfectly stationary. As the temperature still decreases, the same phenomenon is repeated, and the magnetic power increases until it attains its maximum. On account of the many difficulties attendant upon the determination of very high temperatures, he does not attempt to fix the point at which iron becomes susceptible of magnetic excitation, but, by cooling a bar in water, he found it to be about 1000° C.

Dr. Mauritius infers from this that iron and steel are incapable of being magnetized when at a white heat, and mentions, *en passant*, that Faraday has already shown that they do not assume the dia-magnetic condition under similar circumstances. After having remarked upon the insufficiency of any of the present theories of magnetism to explain the phenomena which he has pointed out, he attempts to account for the sudden appearance of the magnetism, when the bar has cooled to a certain temperature, in the following manner:—"I look upon iron has having a binary composition (Fe + Fe), and that this binary character is somehow connected with its magnetic properties. At very high temperatures the double atoms become separated, and magnetism ceases. This occurs at a certain fixed point, and, when the temperature has sunk below this point, the atoms recombine and magnetism begins. The manifestation of the presence of the magnetism, as seen through the telescope, is as though a chemical change were being propagated through a compact mass: witness the formation of sulphuret of iron. When the double atoms have become separated, the iron is in a nascent state. I anticipate no objection, on chemical grounds, when I instance the decomposition of water by red-hot iron. The property of welding may also be explained on a similar hypothesis."

Dr. Mauritius is not prepared to give a satisfactory explanation of the non-continuity of the magnetism, so especially marked in the case of steel; but he imagines that it is in some way connected with the presence of carbon. As was first shown by Karsten, the carbon in hardened steel is chemically united with the iron; but this is not the case as regards soft steel. After a careful consideration of these and some other similar facts, he seems inclined to think "that the presence of carbon in steel, at this temperature, induces a wide-spread chemical or molecular change, which is less apparent in cast iron, and disappears altogether in the case of wrought iron.

THE IDENTITY OF LIGHTNING AND ELECTRICITY.

The mode in which this great discovery was suggested to Dr. Franklin, we give in his own words, extracted from his autobiography:—

"In 1746, living then in Boston, I met with Dr. Spence, who was lately arrived from Scotland, and showed me some electrical experiments. They were imperfectly performed, as he was not very expert; but, being on a subject quite new to me, they equally surprised and pleased me. Soon after my return to Philadelphia, our library company received from Mr. Peter Collinson, Fellow of the Royal Society of London, a present of a glass tube, with some account of the use of it, in making such experiments. I eagerly seized the opportunity of repeating what I had seen in Boston; and, by much practice, acquired great readiness in performing those also which we had an account of from England, adding a number of new ones. I say much practice, for my house was continually full, for some time, with persons who came to see those wonders.

"To divide a little this encumbrance among my friends, I caused a number of similar tubes to be blown in our glass-house, with which they furnished themselves, so that we had at length several performers. Among these the principal was Mr. Kinnersley, an ingenious neighbour, who, being out of business, I encouraged him to undertake showing the experiments for money, and drew up for him two lectures, in which the experiments were ranged in such order, and accompanied with explanations in such method, as that the foregoing should comprehend the following. He procured an elegant apparatus for the purpose, in which all the little machines that I had roughly made for myself were neatly formed by instrument-makers. His lectures were well attended, and gave great satisfaction; and after some time he went through the colonies, exhibiting them in every capital town, and picked up some money. In the West India Islands, indeed, it was with difficulty that the experiments could be made, from the general moisture of the air.

"Obliged as we were to Mr. Collinson for the tube, &c., I thought it right he should be informed of our success in using it, and wrote him several letters containing accounts of our experiments. He got them read in the Royal Society, where they were not at first thought worth so much notice as to be printed in their *Transactions*. One paper, which I wrote for Mr. Kinnersley, on the sameness of lightning with electricity, I sent to Mr. Mitchell, an acquaintance of mine, and one of the members also of that society; he wrote me word that it had been read, but was laughed at by the connoisseurs. The papers, however, being shown to Dr. Fothergill, he thought them of too much value to be stifled, and advised the printing of them. Mr. Collinson then gave them to Cave, for publication in his *Gentleman's Magazine*, but he chose to print them separately in a pamphlet, and Dr. Fothergill wrote the preface. Cave, it seems, judged rightly for his profession, for by the additions that arrived afterwards, they swelled to a quarto volume, which has had five editions, and cost him nothing for copy-money.

"It was, however, some time before those papers were taken notice of in England. A copy of them happening to fall into the hands of the Count de Buffon, a philosopher deservedly of great reputation in France, and indeed all over Europe, he prevailed with M. Dubourg to translate them into French; and they were printed at Paris. The publication offended the Abbé Nollet, Preceptor in Natural Philosophy to the Royal Family, and an able experimenter, who had formed and published a theory of electricity, which then had the general vogue. He could not at first believe that such a work came from America, and said it must have been fabricated by his enemies at Paris to oppose his system. Afterwards, having been assured that there really existed such a person as Franklin at Philadelphia, which he had doubted, he wrote and published a volume of letters, chiefly addressed to me, defending his theory, and denying the verity of my experiments, and of the positions deduced from them.

"I once purposed answering the Abbé, and actually began the answer, but, on consideration that my writings contained a description of experiments which any one might repeat and verify, and if not to be verified, could not be defended, or of observations offered as conjectures, and not delivered dogmatically, thence not laying me under any obligation to defend them, and, reflecting that a dispute between two persons, written in different languages, might be lengthened greatly by mistranslations, and thence misconceptions of one another's meaning—much of one of the Abbé's letters being founded on an error in the translation—I concluded to let my papers shift for themselves, believing it better to spend what time I could spare from public business in making new arrangements, than in disputing about those already made. I therefore never answered M. Nollet, and the event gave me no cause to repeat my silence, for my friend, M. Le Roy, of the Royal Academy of Sciences, took up my cause and refuted him; my book was translated into the Italian, German, and Latin languages, and the doctrine it contained was by degrees generally adopted by the philosophers of Europe, in preference to that of the Abbé, so that he lived to see himself the last of his sect, except Monsieur B——, of Paris, his *élève* and immediate disciple.

"What gave my book the more sudden and general celebrity was the success of one of its proposed experiments, made by Messieurs Dalibard and De Lor at Marly, for drawing lightning from the clouds. This engaged the public attention everywhere. M. De Lor, who had an apparatus for experimental philosophy, and lectured in that branch of science, undertook to repeat what he called the 'Philadelphia Experiments,' and, after they were performed before the king and court, all the curious of Paris flocked to see them. I will not swell this narrative with an account of that capital experiment, or of the infinite pleasure I received in the success of a similar one I made soon after with a kite at Philadelphia, as both are to be found in the histories of electricity.

"Dr. Wright, an English physician, when at Paris, wrote to a friend, who was of the Royal Society, an account of the high esteem my experiments were in among the learned abroad, and of their wonder that my writings had been so little noticed in England. The Society, on this, resumed the consideration of the letters that had been read to them, and the celebrated Dr. Watson drew up a summary account of them, and of all I had afterwards sent to England on the subject, which he accompanied with some praise of the writer. This summary was then printed in their *Transactions*,

and some members of the Society in London, particularly the very ingenious Mr. Canton, having verified the experiment of procuring lightning from the clouds by a pointed rod, and acquainted them with the success, they soon made me more than amends for the slight with which they had before treated me. Without my having made any application for that honour, they chose me a member, and voted that I should be excused the customary payments, which would have amounted to twenty-five guineas, and ever since have given me their *Transactions* gratis. They also presented me with the gold medal of Sir Godfrey Copley, for the year 1753, the delivery of which was accompanied by a very handsome speech of the president, Lord Macclesfield, wherein I was highly honoured."

Dr. Franklin afterwards, in a letter to a friend in England, gave a full account of his experiment with the kite:—

"While he was waiting for the completion of a spire which was being erected in Philadelphia, it occurred to him that he might raise a lightning-rod in the air by means of a kite. He accordingly constructed a light cross of cedar wood, which he covered with a large, thin silk handkerchief. Into the upper end of the kite he inserted a pointed wire about a foot in length, and connected this with a string which was of hemp. The lower end of the string was terminated by a silk cord, and at the junction of the hemp and silk was attached an iron key. He then waited for the approach of a thunder-shower, and seeing a cloud arising, he took his son with him, and going out of the city raised his kite. For a considerable time there was no manifestation of electricity, the cloud passing over the kite without producing any effect, and he began to despair of success. After a time, however, he saw the fibres of the hemp string bristling out, and, presenting his knuckles to the key, he received a spark. After it began to rain and had wet the string, increasing its conducting power, the sparks came in profusion."

This experiment was made in June, 1752, and Franklin was then forty-six years of age. Though similar experiments had been made just previously, by Dalibard and De Lor, in France, yet, as those were made in accordance with directions furnished by Dr. Franklin, the credit of the discovery is fully awarded to him by the most eminent French writers, including De la Rive.

The discovery immediately attracted universal attention, and the experiment was repeated throughout Europe. In St. Petersburg it cost one learned professor his life. Professor Richman was engaged in writing a work on the electricity of the atmosphere, and had erected a lightning-rod on his house. In the forenoon of August 6th, 1753, he was attending a regular meeting of the Academy of Sciences, when he heard distant thunder, and immediately hastened home to observe his rod, taking with him his engraver, Sokolow, to witness the phenomena, so that he might be able to represent them. The lower end of Professor Richman's rod terminated in a glass jar, and he had attached a light string to the rod to indicate the degree of electrical excitement. The string was standing at 4°, and Professor Richman was explaining to Mr. Sokolow the extreme danger if it should rise to 45°, when there came a terrible clap of thunder, that startled all St. Petersburg. Professor Richman stooped down to look at his electrometer, when, Mr. Sokolow says, a ball of fire, as big as his fist, darted from the rod into the professor's head. He fell back dead. A red spot was found on his forehead, the shoe of his left foot was split open, and the skin was burned in a few places on his body.

Dr. Franklin immediately turned his thoughts to the application of his great discovery to some useful purpose, and suggested the lightning-rod, by which the thunderbolt is drawn in silence from the clouds, and the most dreaded of all the forces of nature is robbed of its terrors.

Improved Lightning-rod.—This form of lightning-rod is of the non-insulated class, and is constructed of pure cold-rolled Lake Superior copper. The conductor itself is of a flat form, and is fastened in close contact with the building it is intended to protect. It is continuous in length, and is supported at various intervals by straps of the same material nailed to the house, the ends of the straps being turned over to make a neat appearance. The upper portion of the rod may be coiled up in a tubular form, to compose the tip and point; the flat shape also permits the conductor to be easily rolled up for transportation. The fact of this conductor being continuous throughout its entire length, without a joint, is a valuable feature, as electricity passes over a smooth surface much more readily than where joints or breaks occur. The close connection between the conductor and the building, the inventor states, is a safeguard against ascending as well as descending currents, and it is claimed that the general arrangement of this continuous non-insulated conductor is safer—much more convenient for adjustment and transportation—than those ordinarily in use.

THE INTERNATIONAL EXHIBITION, 1862.

(Continued from page 235.)

M. Gloesener, Liége, M. (Belgium, 349), exhibits a chronoscope, in which many of the difficulties attending these delicate instruments have been successfully overcome. He avoids the use of soft iron altogether, and marks the instant at which the current ceases to pass through a given circuit by means of a sensitive galvanometer. One end of the needle of this galvanometer is provided with a little point, which, when the circuit is broken, is brought for an instant into contact with the blackened surface of a revolving cylinder. The very deflection of the needle, however, re-establishes the current through a second circuit, and lifts the point away from the revolving cylinder, leaving a little speck as the mark of the instant at which the needle fell. The moment at which the second circuit is broken can be similarly registered, and the current is instantly established in a third circuit, which in its turn can serve for a third observation. The little point at the end of the galvanometer needle is so arranged as to make a differently-shaped mark on its first deflection to that which it subsequently produces. This is done to mark the starting point. The cylinder, coated with lamp-black, revolves rapidly, making about four revolutions per second. Another cylinder, geared with the first, and revolving much less rapidly, is marked at the same instant by a second galvanometer needle. The marks on the first cylinder show the fractions of less than one quarter of a second, separating two observations; and the marks on the second cylinder show whether more than one quarter of a second has elapsed between the two observations, and if so, how many. The first cylinder is divided into 500 parts, and allows of approximate measurement to the 10,000th of a second. The speed is controlled by a fly aided by a governor, in which two diverging balls, such as are used in Watt's governor, lift one end of a set of jointed levers, the other end of which presses a small spring against one end of the revolving cylinder. It is said that this method of governing the speed gives sufficiently accurate results, and it is certainly not without merit. The divergence of the balls is, it will be observed, quite unaffected by the use made of the spring to retard the movement: a condition favourable to uniformity of motion, generally, if not always, neglected hitherto. The apparatus is driven by a weight of twenty kilogrammes, and remains in motion for about twenty-five minutes. The marking point of the galvanometer is placed about one millimetre distant from the revolving cylinder. The needle is light, so that it can be made to fall and rise with great rapidity by a small force; and, moreover, on the cessation of the current, its fall will occupy sensibly the same time on different occasions. The defects arising from the use of soft iron are thus entirely avoided.

M. Gloesener exhibits several ingenious arrangements, by which the current can be re-established in fresh circuits after each interruption; but this part of the mechanism may be varied almost indefinitely. The initial speed of bullets can be shown on this apparatus by the fracture of wires placed within two or three yards of one another, so rapidly does the galvanometer point fall and rise.

M. Gloesener also exhibits another chronoscope of much simpler construction, which seems extremely well adapted for experiments, in which the time to be measured does not exceed about one quarter of a second. This instrument consists of a galvanometer similar to that already mentioned, leaving its marks on a divided limb, forming part of the bob of a pendulum. It resembles Navez's instrument, inasmuch as the time separating the two marks is required to be deduced from the period of oscillation of the pendulum, but differs from it considerably, inasmuch as the observations are registered directly instead of indirectly. Moreover, it dispenses with soft iron, and allows two or more events to be registered during one oscillation of the pendulum.

T. Jaspar, Liége, H. M. (Belgium, 350), exhibits a chronoscope known as Navez's pendulum chronoscope, an instrument extensively used both abroad and in this country. This apparatus consists of three distinct parts. 1st. The pendulum with its immediate accessories. 2nd. An apparatus for making a contact at a given time after a certain circuit has been broken. 3rd. An apparatus for breaking two circuits simultaneously. These two last parts may be simply called the contact-maker and contact-breaker.

The pendulum is fitted with two electro-magnets—one used to hold it at one extremity of its oscillation by attracting a little piece of soft iron let into the bob; the other, to stop a very light aluminium index centred on the axis of the pendulum, and carried round with

it by the light friction of a spring, until a current passes round this second electro-magnet, which then stops the index by attracting an iron collar fitted to its hollow axis, but allows the pendulum to continue its oscillation freely. A vernier on the end of the index allows the exact arc described in passing from the first to the second position of rest to be accurately read on a fixed graduated limb. Thus the interruption of a current through one circuit starts the pendulum and index simultaneously, and the establishment of a current in a second circuit stops the index, showing the arc traversed in the interval. It will readily be understood that the velocity of the pendulum, in falling through various arcs, can be determined by direct experiment.

The speed of the projectile in this as in other chronoscopes is measured by the time elapsing between the successive fractures of two wires, but in the present case the measurement is indirect. The nearest wire screen forms part of a circuit which includes the electro-magnet used to restrain the pendulum, but the farther wire screen is not directly connected with either of the pendulum electro-magnets, but it is connected with the electro-magnet of the contact-maker. This electro-magnet carries an armature, which drops off when the circuit is broken, and falls on to a spring furnished with a contact point, adjusted close to the surface of some mercury in a little cup. The fall of the armature makes contact between the mercury and the spring, and by so doing completes a circuit through the second electro-magnet of the pendulum, and stops the index. Thus, when a ball passes through the two wire screens in succession, it first breaks the first circuit, and starts the pendulum; it next breaks the second circuit, and lets fall an armature, which completes a third circuit, and stops the index. The arc can then be measured, which corresponds to the time elapsing between the moment when the pendulum started and that when the index stopped. But this period of time depends on many elements: 1st. The time required by the first electro-magnet to lose its magnetism. 2nd. The time required by the electro-magnet of the contact-maker to lose its magnetism. 3rd. The time occupied by the fall of the armature. 4th. The time required by the second pendulum electro-magnet to acquire sufficient force to stop the index; and 5th. The time of flight between the two screens. The contact-breaker is used to eliminate by a separate observation the first four of these elements, leaving the fifth, which is alone required. This is simply and easily effected by establishing all the circuits as before, and breaking the two wire screen circuits simultaneously. All the events will occur in the same sequence as before, except the rupture of the two circuits, and as all the other circumstances remain similar, they will occupy in the aggregate exactly the same time as they must have done in the previous experiment, and the index will be arrested after it has traversed an arc B, measuring their duration; if, then, A be the arc traversed in the former experiment, the difference, A — B, will measure the time of flight between the screens in the first observation. This measurement is required to be reduced into seconds by calculations of an obvious character.

The great merit of this chronoscope has been proved by its extensive use; but it is difficult to believe that it can give thoroughly accurate results. The calculation of the time occupied by the bob in traversing each part of the limb takes no account of the friction or of the resistance of the air. It is difficult to observe accurately the elements required to calculate this period of oscillation. Electro-magnets are seldom in the same condition, even during two successive experiments, and no less than three electro-magnets are required in this apparatus. There is always some risk that the contact-breaker may not break the two circuits at exactly the same moment. The friction employed to carry round the index may be too small, and the index will then lag behind the pendulum at starting, or the friction may be too great, and drag the soft-iron collar or the index past the electro-magnet some uncertain time after its circuit is completed. Nevertheless, this instrument is in great repute, probably owing to the simple plan of referring the velocity of the projectile directly to the velocity of a pendulum; but it certainly seems probable that the apparatus would be much improved by dispensing with all the electro-magnets, contact-makers and breakers, with the substitution of a direct observation recorded by an induction spark as in Hardy's chronoscope, or by a galvanometer needle such as M. Gloesener adopts.

The galvanometer chronoscope used by M. Pouillet and by M. Helmholz is, unfortunately, not represented in the Exhibition.

7. *Chronographs.*

Chronographs may be described as chronoscopes, in which the times registered depend on a signal sent by the voluntary effort of the observer, instead of by the automatic action of the apparatus.*

The Telegraphen Werkstätte of Berne (Switzerland, 151) exhibit a chronograph for registering the instant at which any observation is made—for instance, the passage of a star.

A strip of paper is moved along by clockwork, driven by a weight, and governed by a fly. The latter is so arranged, that on any slight increase of speed, the axis of the fly is pressed against a steel spring, increasing the friction, and acting as a break. The strip of paper is permanently pressed against two little revolving discs placed side by side, and receiving ink from felt rollers, as in Digney's ink-writer. These two discs, when not interfered with, produce two straight parallel lines side by side on the paper. Two electro-magnets, with two distinct circuits, are used, with armatures so connected with the supports of the two revolving discs, that a momentary current sent round either magnet moves the corresponding disc a little way across the paper, making a little nipple on one of the black lines. The pendulum of a clock closes the circuit of one of the electro-magnets once every second, and nipples are consequently produced on one line, separated by lines representing seconds of time. The circuit through the other electro-magnet is completed at any required moment by the observer with the aid of a common contact key. The nipples so produced on this line, by comparison with those on the first, fix the time of each observation recorded. The "second" nipples are about ten millimetres apart, and intervals of time of less than one-tenth of a second can therefore be accurately shown by this instrument.

H. Ausfeld, Gotha, M. (Saxe-Coburg, 2,625), exhibits a similar apparatus for registering astronomical observations, which differs from the last described in detail only. This instrument consists of clockwork used to draw forward a strip of paper, and regulated roughly by a centrifugal pendulum. Two electro-magnets are used with their armatures; one, worked by pendulum contacts from an astronomical clock, marks the seconds by dots on the paper; the other makes a dot by the side of the former when a button is pressed by the observer at the instant of an observation. The relative position of this dot with the others marks the time of each observation. The observer has also the means of stopping the clockwork at will, and starting it by an electric current at any given moment. This instrument was designed by Dr. A. Hansen, and is used in the Gotha and Leipsic observatories.

An excellent electric chronograph is also exhibited by M. Krille, Altona, Class XV. (Denmark, 136). This instrument arrived too late to be inspected by the jury, or, in the writer's opinion, a medal would certainly have been awarded to the exhibitor. In this instrument a cylinder covered with blackened paper, driven by clockwork, and regulated by a conical pendulum like that in Hardy's chronoscope, revolves at sensibly uniform speed. Two diamond points on the ends of two levers are pressed against the cylinder as it revolves, and mark two fine white lines on the blackened surface. These levers are carried on a sort of car, to which a slow motion of translation is given parallel to the axis of the cylinder, so that the lines marked are helical and continuous. The levers are, moreover, connected with the armatures of two separate electro-magnets, also carried on the car. These armatures, by their motion, can produce a slight independent movement of translation in the diamond points along the surface of the cylinder. One of these electro-magnets is worked by contacts from a standard clock, so contrived as to produce a broken line equally subdivided, thus ‾|_|‾|_|‾. The instant of the change of contact is thus singularly well and sharply defined. The second electro-magnet is worked by the observer with a key, and produces a little nipple, fixing the instant of observation by its position on the cylinder relatively to the broken or "second" line. So far the arrangements, although extremely good, can hardly be called novel. The manner of obtaining the contacts from the standard pendulum is, however, not only excellent, but, so far as the writer knows, quite new. Two short vertical glass tubes placed side by side have each near their lower end a small horizontal branch, the two open ends of which are placed in very close proximity opposite each other. The two larger tubes are partly filled with mercury, which flows through the two horizontal branches until the two streams join in the open space between them. This space is, however, so small that capillary attraction

* The writer drew this distinction between the words chronoscope and chronograph from the consideration that the one instrument is used to observe a certain short interval of time, and the other to write or record the time at which a certain phenomena occurs. Professor Wheatstone has pointed out to him that a different distinction was drawn in the original use of the words. Chronoscope was then used to signify an instrument by which the interval of time could be observed, and chronograph an instrument by which it could be recorded.

prevents the mercury from falling down, so that it is entirely retained inside the tubes, with the exception of this one short, exposed, and apparently unsupported drop hanging between the two branches. A very thin sheet of mica is carried by an arm on the pendulum, so placed that at each beat the mica sheet descends between the ends of the two little branch tubes, separating the mercury in the two reservoirs, and breaking all electrical connection between them. At the return of the pendulum the mica sheet is withdrawn, and the mercury from the two sides joins as before, making an electrical connection. The action of this admirable make and break arrangement seems all that could be desired; the mercury is not spilt, as might be expected, and the contact appears to be made with perfect certainty and regularity. The friction must be almost nothing; and if, as appears probable, the oxide formed by each spark is removed by the mica plate in its descent, this plan might be very advantageously applied to all electric clocks and galvanometer relays. The workmanship of the instrument is excellent.

Mouilleron & Vinay, Paris, M. (France, 1,438), exhibit a chronograph of apparently very complicated construction. The writer was unable to obtain any description of this instrument.

8. *Electric Lamps.*

A considerable number of self-acting regulators for the electric light are exhibited. Carbon electrodes are used in all these lamps, and the general object aimed at is the maintenance of a constant current through these electrodes. In all, the current is passed round an electro-magnet, the armature of which allows the approach of the two carbon points when the strength of the current falls below a certain amount. The resistance of the circuit is thus diminished, and the current re-established at the desired strength. As the points are consumed the resistance again increases, the current is weakened, and the armature allows of a further approach. In some of the lamps provision is made for separating the electrodes when the current is too strong. It is clear that this principle will never lead to perfect constancy in the light, so long as any variation occurs in the electro-motive force of the source of electricity employed, or where great variations occur in the resistance, or composition of the carbon electrodes; for instance, it is clear that, in order to allow equal currents to circulate with a weak and strong battery, they must remain very slightly separated in the first case, and at a considerable distance apart in the second case. The light under these two conditions cannot be the same. Nevertheless, convincing proof has been given that where the source of electricity is sensibly constant, as is the case with a magneto-electric engine driven at a constant speed, the light may with electrodes of good quality be maintained sensibly constant.

L. J. Duboscq, Paris, M. (France, 1,420), exhibits a lamp which is extensively used for optical experiments.

The two carbon electrodes are fixed one over the other, on frames connected by racks and gearing, so that when the upper electrode descends, the lower one rises. The wheelwork is so arranged, that the relative motion of these two electrodes shall be such as to compensate for the well-known unequal consumption of the positive and negative carbon electrodes. The light is maintained in a constant position by this arrangement, which would not be the case if only one electrode were moveable, and the other fixed, or if the two moved through equal distances; a barrel spring is employed to drive the clockwork which moves the electrodes. This clockwork is stopped by a detent which gears with an escapement wheel. The detent is connected with the armature of an electro-magnet, and allows one or more teeth of the escapement wheel to pass whenever the current is below a certain strength. Thus, step by step the carbon points are allowed to approach. In order to light this lamp one of the carbon electrodes must be brought in contact with the other by hand, and then removed to a certain distance; this can be done without interfering with the train of wheels. The distance from each other at which the electrodes remain, or rather the strength of current at which the escapement wheel is freed, can be regulated by altering the distance between the electro-magnet and its armature, and thus altering the attraction between them for a given current.

This lamp is said to answer excellently for experiments, or for the lecture-room; it is not suited to lighthouses or for public lamps, because, if extinguished by any accident, it is not spontaneously relighted. It moreover requires to be stopped as well as started by hand, otherwise the carbon sticks would be forced together by the clockwork until they become jammed or broken.

M. Duboscq exhibits another lamp of very similar construction, in which only one of the two electrodes moves, and the light, therefore, gradually changes its position.

J. Jaspar, Liége, H. M. (Belgium, 350), exhibits a very simple form of regulator.

The electrodes both move, and are so connected by cords and pullies that their relative motion is in proportion to their consumption. The weight of the upper frame and electrode is somewhat greater than that of the lower frame, and when slightly loaded, is used to put the system in motion; a soft-iron cylinder attached to the lower frame enters for about half its length into a suction coil. When the current attains a certain strength, the suction produced in this coil, added to the weight of the lower frame, exactly counterbalances the weight of the loaded upper frame and electrode, and the further approach of the electrodes is stopped; but as these wear away, the soft-iron core rises slowly in the suction coils, so as to maintain a nearly constant strength of current. In this form there is no intermittence in the light, which, moreover, remains sensibly in one spot. It must, however, be lighted by hand, by first bringing the two points together, and then separating them. Moreover, the current cannot remain perfectly constant, for the attraction produced by a given current on the soft-iron cylinder varies as this cylinder rises in the coils. The adjustment by which the distance of the points or the strength of current is determined is made by simply adding or removing small weights, such as shot, to or from the top or driving frame. Any change in the friction of the moving parts would require a fresh adjustment of this weight. The lamp has, however, the merit of extreme simplicity.

(To be continued.)

THE TELEGRAPH IN SPAIN.

In a recent number we alluded to the great zeal with which, amongst other well-considered measures, the Minister of Spain is endeavouring to forward all matters connected with telegraphy. We have now much pleasure in publishing the following papers, shewing what has already been achieved for telegraphy, the increase of free intercourse, the progress of commerce, and the welfare of that nation. We congratulate the young Minister, Senor Antonio Cánovas del Castillo, who so well understands how to develope all matters connected with the prosperity of his country, and let us render him the honour to which he is so much entitled, in order to encourage him to continue in office, which his excessive modesty has made him shun so often, but in which he daily gives evidence of administrative capacity of high order.

Petition to Her Majesty.

Madam,—For some time past your Majesty's Government has been endeavouring by various means to place telegraphic correspondence on such a footing of facility and economy, as to make it correspond with its important objects and the wishes of the public.

There are still several important measures to be adopted, and the government proposes to study and establish them as speedily as possible.

The surcharge of a real for each inland telegram, known as porterage, the profit of which is applied, by Royal order, to provide for the deficiency of the salaries of clerks charged with the maintenance of lines and service of the stations, forms an obstacle to the development of the telegraphic service, in spite of the smallness of its amount. The government being convinced of this, has taken care in the present budget, submitted to the Cortes, to suggest the necessary alterations, so that, without burdening the treasury, but rather assisting it by means of a new organization of the service, in which considerable economy has already been decreed, they may be able to suppress this tax upon correspondence, and obtain a sensible reduction in the cost of inland telegrams, a perfect harmony and simplicity in the tariffs, regulating them strictly according to the length of each despatch, an exact uniformity between the regulations and cost of Spanish inland correspondence, and those which govern the international communications, and lastly, what is more important still, the disappearance of the principal obstacle against establishing the system of franking by stamps instead of actual payment of telegrams.

This measure, then, accompanied by the new organization applied to the service of transmission, and, by the latitude granted by Royal decree, dated the 30th of March, will surely increase the facilities claimed by the public, for utilising the telegraph, and will greatly assist in diminishing the deficit which weighs so heavily upon this important branch of public administration.

For these considerations the Minister hereto subscribing has the honour of submitting to your Majesty the annexed proposed decree.

At your Majesty's R. F.,

Antonio Cánovas del Castillo.

ROYAL DECREE.

In conformity with what the Minister of State has proposed to me, I have decreed as follows :—

Art. 1. From the 1st of next May the extra fee for porterage, with which the inland correspondence is surcharged, will cease.

Art. 2. The cost of such telegrams will from the 1st of July be reduced to the uniform rate of four reals for every message of ten words.

Done at the Palace, on the 21st day of April, 1864.

I THE QUEEN.

The Minister of State for Home Affairs,
Antonio Cánovas del Castillo.

MINISTRY OF STATE.

Arrangement entered into between Spain and France for equalising and diminishing the rate of the present tariff of prices for transmission of telegraphic messages.—Signed in Paris on the 30th day of December, 1863.

The Government of Her Majesty the Queen of Spain and the Government of His Majesty the Emperor of the French, anxious to obtain for their respective countries the advantages of an equalised tariff for transmission of telegraphic messages, and with the view of increasing them by reducing the price, have for that purpose given authority to the undersigned, the Ambassador of Her Catholic Majesty the Queen of Spain and the Minister of Foreign Affairs of His Majesty the Emperor of the French, who have agreed to the following terms:—

All the despatches which will pass through Spain (including the Balearic Islands) and France (including Corsica) will pay the rate of four francs per message of twenty words, no matter from what telegraphic office they proceed, or to what station they are addressed. Each ten words, or part of ten words, beyond twenty, will pay half the amount of a single message.

The amount of every message will be divided equally between the two Governments.

It is also agreed that if, in consequence of any interruption of the direct submarine communication between France and Corsica, it should be necessary to transmit the messages from Spain to that island through a foreign line, they should, in respect of payment, be subject to the general conditions of existing international treaties.

The conditions established by the decree dated 29th of April, 1859, respecting the cost of these messages transmitted on the frontier from one station to another, are repealed.

The cost of a single message transmitted from France to Algeria, or *vice versa*, passing through the Spanish or submarine lines, as also of the messages between Spain and Algeria, transmitted either by land or French cables, will always be eight francs. The messages received or forwarded to Tunis will pay two francs more.

The amount of these messages will always be divided in the proportion of three francs to Spain, and five or seven francs to France, according to whether the despatch be to Algeria or to Tunis.

The messages exceeding twenty words will have to pay an extra charge, in accordance with the rule already established.

To avoid the difficulties which might occur in consequence of the different coinage of the two countries, it has been agreed that the international accounts, made up in the usual form, shall be presented by Spain in Spanish figures, but at the same time its amount reduced into French figures; and by the French administration in French money, also reducing the amount into Spanish figures.

The reduction of the money will be made at the rate of nineteen reals vellon for every five franc piece.

So far as inconsistent with the present act are repealed the conditions of the ninth article of the decree signed on the 24th December, 1863, which runs thus :—

"The submarine communication from Oran to Carthagena will have to pay one franc fifty cents for messages forwarded either from Spain or Portugal to Algeria."

This agreement is established for an indefinite period, and will last until denounced by either of the contracting states; in that case it will continue in operation a year beyond the date of such denunciation.

The stipulations of this agreement will come into operation on the 1st of January, 1864.

The present agreement will be ratified, and the ratifications will be exchanged in Paris as soon as possible.

Done in duplicate, in Paris, on the 30th of December, 1863.

(L. S.) Signed, TAVIERDE ISTURIR.
(L. S.) Signed, DROUYN DE LHUYS.

This agreement has been duly ratified by Her Catholic Majesty and by His Majesty the Emperor of the French, and the ratifications were exchanged in Paris on the 8th of the present month of April.

MAGNETIC GLOBE.—This is a new and ingenious invention by Mr. Elbert Pere, of Brooklyn, N.Y., and consists in the production of geographical globes with magnetic powers, by making them of a metal possessing magnetic properties, so that small objects, also possessing magnetic properties, will be attracted and adhere to the surface of the globe, and thus enable the illustration to the eye of the principle of the power of the earth's attraction —a physical fact which teachers have heretofore found difficult to demonstrate successfully to the minds of the young.

LIGHTING GAS BY ELECTRICITY.

MANY attempts have been made from time to time to effect the simultaneous ignition of a great number of gas-jets by the aid of electricity. Thus, all the lamps, not alone in a single street, but in an entire district, might be lighted in a single instant of time, and, in addition to the convenience of such an arrangement, an actual saving of gas would be effected, because, now, certain lamps have to be lit too early in order that others may not be lit too late. In theatres, concert-rooms, churches, &c., it is obvious that great advantages would follow on the successful employment of any system of electrical simultaneous ignition.

Hitherto this has been proposed to be effected by a wire running from jet to jet, the circuit being partially interrupted by the introduction of a filament of platinum in proximity with the orifice through which the gas issues. This filament becomes red hot when a strong current of electricity is transmitted through the wires, and thereby lights the gas. One or two other expedients have been adopted, but hitherto with very partial success. But, although the simultaneous ignition of a number of jets cannot be effected with certainty, it seems far from improbable that the ubiquitous lucifer will be superseded by very simple and elegant arrangements. At a recent meeting of the Franklin Institute, Philadelphia, Messrs. Cornelius & Baker exhibited a very beautiful method of lighting gas by means of frictional electricity, arranged for use with a bracket, two portable lighters, and a table light, all being simple in arrangement and readily kept in order. These instruments are constructed upon the principle of the electrophorus. The electric bracket is arranged with a brass cup in the form of a vase, resting upon the bracket, with a connecting piece of hard rubber. This cup is lined with lamb-skin covered with silk, and contains the hard rubber electric piece which corresponds in form to the inside of the cup. A coiled covered wire connects the brass cup with a wire attached to the burner, and terminating just above the burner. In order to light the gas the stop is turned, the hard rubber piece lifted partly from the cup, thus liberating the spark and lighting the gas. The Portable Lighter consists of the same vase or cup, with the addition of a non-conducting handle. When the brass cup is lifted from the electric piece and held to the conducting wire of the burner, the gas is immediately lighted. Another portable instrument, called the Double Air-tight Electrophorus, consists of two metallic tubes, each closed at one end, and connected together at the other, with a non-conducting ring of hard rubber, the inside being lined with lamb-skin. A hard rubber rod is placed within them the length of one of the tubes, and fitting them so as to move somewhat freely from end to end. When the moveable piece inside is allowed to fall to one end, and the tube is raised to the connecting wire of the burner, this piece changes its place again, falling into the tube held by the hand. The spark leaves the upper end of the tube at the same time and lights the gas. The Table Light Burner consists of the same instrument arranged upon a pivot regularly attached to the pillar light. The subject is worth the attention of gas engineers here, and we feel little doubt that simple, inexpensive, and elegant little instruments of the kind we have described would soon become popular among us.—*Building News.*

THE ELECTRIC LIGHT AND PHOTOGRAPHY.

ABOUT three years ago, Dove received from Mr. Gunther, of Berlin, a photograph of a bronze statue of an amazon holding a lance in a perpendicular position, Mr. G. at the same time calling his attention to a singular mark in the picture, which was not in the original. The lance was properly delineated on the negative plate, but in addition, just at its tip, a dark streak was visible, though nothing of the kind had been observed at the time of taking the picture. Careful examination of the plate showed two other analogous marks. Dove thought that these singular appearances might have been caused by the presence of invisible electric brushes, resting on these points, and undertook some experiments to determine whether weak electric light could be photographed. Geisler tubes were used in a dark room, and, with the aid of Gunther, he succeeded in obtaining good photographs of the stratified discharge, as Professor William B. Rogers had done some months previously. This led Professor Rood, of Columbia College, to attempt the study of the electric brush by the aid of photography, but as its light is incomparably weaker than that from the Geisler tube, he found that no impression was produced on the sensitive

plate. Being unwilling to abandon the matter, a very sensitive collodion was then prepared from pyroxyline, in which the cotton fibre was somewhat disintegrated, and by its use good photographs were finally obtained of the positive as well as of the negative brush. An ordinary camera was employed, and the exposure lasted seven minutes. The minute photographs were then enlarged as usual, and prints made from the enlarged negatives.

The positive electrical brush consists, as is well-known, of a short stem, with widely-branching ramifications; these latter are very faint, even in the darkest room, and failed to produce an impression on the plate. The stem of the brush, which is somewhat more luminous, delineated itself very satisfactorily. It is well known that the negative brush is much smaller than the positive, and it is often spoken of as a star or minute point of light; the photograph, however, shows that this is not the case, but that its structure is analogous to that of the positive brush, only that the ramification begins lower down on the stem, as it were, nearly at its root.

Action of weak electric light on the plate in the presence of daylight.—The Geisler tubes, in the physical cabinet of the college, enabled Professor Rood now to put the probability of Dove's suggestion to the test of experiment; some of these were connected with an induction coil, and photographed in broad daylight, when it was found that the image formed by the electric discharge could be easily traced through the length of the tubes, and that even the stratification was still partially visible. In these cases, however, the electric light was still visible to the eye during the discharges.

Accordingly, to make an exact experiment on this point, a sheet of white paper was placed behind one of these tubes, and white daylight reflected through it towards the camera. The intensity of this reflected light was so regulated that the bright envelope of the platinum wire was nearly invisible, and the diffused violet light, at a greater distance from the wire, absolutely invisible. Nevertheless, an intense photographic image of the envelope, and a very distinct image of the diffused electric light, was easily obtained, thus proving conclusively the correctness of Dove's assumption, that electric light, which in ordinary daylight could not be seen, owing to its feeble illuminating power, might yet make itself very evident on the iodized plate, by virtue of its high per-centage of chemical rays.

This experiment is indeed a very striking proof of the chemical activity of the electric light, the more so as, according to some experiments, the iodized plate is by no means as sensitive to slight differences in illumination as the human eye.

Among the Geisler tubes belonging to the college was found one in which bulbs of uranium glass were alternated with small tubes of plain colourless glass. When the room was darkened, and the electric discharge passed through it, owing to their fluorescence the balls shone very brightly, invisible or faintly visible light being converted into bright green light. On taking a photograph of the tube, it was quite surprising to see how blank were the spaces on the plate, where the images of the green bulbs had fallen. After an exposure of four minutes only one of the bulbs could be faintly traced, though other portions of the discharge were represented by an intense deposit of silver. This shows how completely the electric light is divested of its chemical power by dispersion from a thin stratum of this kind of glass. It might be supposed that uranium glass would cut off most of the chemical rays when ordinary daylight was transmitted through it, but this was not found to be the case. The Geisler tube with the uranium bulbs was placed so that the light from a bright sky fell directly through it on the lens of the camera; the entire aperture of the lens (a "portrait combination" of six inches focal length) was used, and the exposure lasted one minute. An examination of the negative plate showed that the thin walls of the uranium bulbs had merely diminished to some extent, the chemical power of the rays passing through them. The same experiment with a plate of uranium glass, two-tenths of an inch in thickness, gave a result like in kind, only differing in degree, the chemical intensity of the light being diminished about one-half. This shows, in accordance with theory, that it is mainly the *dispersed* light which has lost its chemical power, and that through a plate of even this thickness many chemical rays still penetrate. A photograph of another Geisler tube, in which the interior discharge tube was surrounded by a solution of sulphate of quinine, was also taken. This liquid, by its fluorescent property, diminished, of course, the intensity of chemical action of the electric light, but by no means to the same extent as the uranium glass.

ON THE PATENT LAWS.

Discussion.

(*Continued from page 237.*)

Mr. Newton Wilson, who said it had been a matter of some surprise that the principle of the patent law should, at this stage of our national history, be called in question, while it was a thing which had been admitted by, he might say, every civilised nation in the world, and by almost every semi-civilised nation, as a necessity of advancing civilisation. He took it that, as a nation advanced in civilisation and in arts, the necessity of giving some encouragement and some protection to the products of inventive genius was absolutely necessary. In what they might call semi-civilised nations, such as Brazil, Chili, and Mexico, patents were given without any Government duty whatever; and why? because they found it necessary to give assistance to enterprise and encouragement to the introduction of new invention in those countries. Gentlemen who objected to the patent law on principle might, with equal justice, object to the legislation recently adopted for the security of trade marks. On the same principle, he could imagine objections to the law of copyright and the registration of designs. He believed that nine-tenths of the members of this Society, if not ninety-nine hundredths of the manufacturing community, would endorse the principle of the patent law, though perhaps they would say it was objectionable in many of its details. There were unquestionably many anomalies in connection with that law. We demanded from the poor inventor a larger sum than was called for in any other part of the globe for what was called the protection of his primitive efforts. If it paid France or Belgium to take a small annual payment, in the one case of £4 a year, and in the other of only ten francs, surely it would be sufficient for the purposes of this country if a corresponding scale were adopted, and he thought it would be found desirable to adopt—not the scale they had now of instalments, which prevented so large a number of patents from reaching the maturity of the final specification and the Great Seal. He thought that system would have to be considerably modified. The payment of a single £5 ought to be quite sufficient to complete a patent, and to meet all the demands of the Government; and if an annual payment of a similar amount were adopted, he believed it would bring a larger amount of revenue than at present, while it would be exacting from the inventor a continuous payment for a continuous interest which he derived from his patent. A particular feature in Belgium was that the patent fees increased year by year on the principle that the patentee was deriving a yearly benefit from his property. He would refer to one or two anomalies in connection with patents. They had at present an arrangement by which it was presumed patents were examined, and it might be imagined that a patent which was not good would not be granted, seeing it had to pass through the hands of the Attorney or Solicitor-General, and fees had to be paid; but this practically afforded no actual check. A large amount of the fees paid by inventors went into the pockets of the Attorney and Solicitor-General, for such services as, he maintained, were totally inadequate. What, then, did they want? He maintained that they wanted a Board of Examiners, who should really examine into the invention and decide whether it was really new, and so avoid the granting of useless patents. They would also be able to tell whether the specification was sufficient. If that were done, we should be saved from much uncertainty and litigation. The next point was the mode of trying patent cases. It appeared to him that for this to be properly conducted with advantage to both sides, there must be a special tribunal. He would have no juries in this court, for it was one where special knowledge was required. There was another point. It would appear that the present patent laws were enacted with a special view to guard the public. It was said by a very able speaker at the last meeting—the Chairman of the Council—that the public were not considered in the provisions of the patent law. He (Mr. Wilson) maintained that they were far too much considered, and that the interest of the inventor was too much disregarded. He maintained that the patent law was so constructed that if an inventor made a mistake in his patent he had the utmost difficulty in correcting it. There was no provision for revising his patent. There was a provision of disclaimer, but that was at the option of the Attorney-General, and, as Mr. Webster knew perfectly well, the Attorney-General might refuse a disclaimer, and then where was the inventor? But the very provision of the disclaimer as it at present existed was defective. It provided that certain words might be struck out, but it allowed the insertion of nothing that would clear the patent of the mystery that previously surrounded it. Another point of importance was patents of importation. In many countries of Europe, and in some of South America, patents of importation were allowed, but the same privileges did not extend to them as were allowed to patents of absolute invention. Here, however, the rights were the same, and the importer might prevent the real inventor from afterwards obtaining protection for his own invention. He knew cases in which the grossest injustice had been inflicted on inventors in that way. He had even known instances in which the inventor had been obliged to purchase the patent back at an enormous cost. Such a state of things, he said, ought to be remedied. It was alleged, at the previous meeting, by Dr. Bachhoffner, that inventors often made it their business to obscure the specification, so as not to allow the real objects of the invention to be clearly shown. From his (Mr. Wilson's) experience this rather arose from the shortcomings of

the patent agents, and he thought that if they had such a court of examiners as had been suggested, it would lead to much greater care on the part of patent agents; and he thought that patent agents themselves should be bound to pass through some curriculum before they put themselves before the world in this capacity. One other point of importance was the necessity for a Patent Museum in this country. Why should we not have something like what they had in the States of America? He conceived the Society of Arts could not do better than to appoint a committee to confer as to the best means of introducing an improved patent law, the provisions of which should, far more than the present one, meet the wants of inventors, manufacturers, and the public.

Mr. Steere remarked that the word "patent" suggested many points for consideration; one was that every patentee was grievously oppressed by law proceedings, as was also the infringer. Now, what was the question to be tried between the parties? It was simply a mere matter of fact, which should be tried before a tribunal of experts, (say a committee of the Society of Arts), and the only parties examined should be the patentee and his workmen on the one side, and the alleged infringer and his workmen on the other. But, as it now stood, the lawyer intervened, and, putting aside matters of fact, argued upon matters of law. It was then often discovered, upon legal reasoning, that the specification was insufficient. So little value did he (Mr. Steere) attach to the specification, that he would abolish it altogether. The simple fact to be decided was, whether an invention was an infringement of a former patent, and to determine that question what consequence was it in what terms the invention was described? By some such plan as he suggested they would relieve both parties of the enormous expenses which attached to the present system of litigation. The case of "Young and Fernie" was a remarkable instance. He would offer another suggestion, which was, that the word "patent" should be dropped altogether, inasmuch as so long as it was retained they never would get rid of litigation. We would prefer that the term "licence" should be used. He contended that the present system of litigation of patent rights required to be placed upon a totally different footing.

Mr. Murdoch said it would take up too much time if he were to attempt to answer the arguments of those who opposed the patent system, or to unravel the intricacy of the statistics which they brought forward. He would, therefore, restrict himself to a few remarks respecting the means proposed for the remedying of evils attendant on that system. He entered upon the subject with diffidence, as he should have to call in question the policy and practicability of the course advocated in Mr. Webster's able paper, respecting the mode of granting letters patent. It was proposed to subject all applications for patents to a preliminary inquiry, made by a tribunal having power to refuse the patent in the case of want of novelty or merit in the invention to be protected.

Mr. Webster said he did not intend that the question of merit should be submitted to such a tribunal.

Mr. Murdoch continued: Now, it seemed to him that such a tribunal would, both in its principle and practical working, be in direct opposition to the spirit of patent law, the chief merit of our present system consisting in the fact of its being an equitable arrangement between the inventor and the public, by which the reward received by the former was in proportion, in some cases, to the benefit conferred by his invention; in all, to the commercial value which attached to any new means for supplying the wants or contributing to the luxuries of society. Further, if property in inventions was to be protected at all, it must be placed upon the same footing as other property, and be secured to its possessor without reference to its value. Every new invention, whether of great or small importance, was deserving of State protection, and the mode of conferring that protection by letters patent was the fairest both to the public and the inventor. If his invention were valuable, it was but right that he should enjoy the profits resulting from its use: these the law secured to him. If, on the other hand, his invention were of trifling value, the hardship (if any), suffered by others, in being forbidden to exercise it, was but small. But if the invention were useless, there were provisions of the law which would meet the case by rendering the patent void, although the patenting of even a useless invention was attended by this beneficial result, that it placed upon record that which had been done in a manufacture, so that that which had been a stumbling-block in the path of one inventor often became a stepping-stone by which subsequent inventors attained success. But if the expediency of making the proposed distinction between inventions were to be granted, he did not see how the principle could be carried into practice. Nine out of ten of the inventions which annually became the subject of patents, were necessarily in a state of infancy when the patents were applied for. This fact was recognised by the law. which granted an inventor provisional protection for six months, in order that he might make such trial of his invention as should satisfy him as to its value, and enable him to describe his invention in its most perfect form in his final specification. If, therefore, the utility of an invention were to be inquired into before the grant of protection, the inventor would be under the disadvantage of having to submit his invention for examination with all those imperfections which could only be removed by repeated experiments, and it would be judged of theoretically instead of upon its practical merits. The examiners, also, however capable and impartial they might be, would, owing to deficiency of evidence, find it difficult to do justice to the cases submitted to them. They would have to try questions of far greater importance than those which were tried by our present tribunals, for, whereas these decided whether an asserted right should or should not be maintained, the examiners would have to decide whether a man should have the power of asserting his right at all, and in doing this they would be without the facilities which were now afforded in our courts of law by the examination of witnesses conversant both with the old methods of practising a manufacture and with the new method in dispute. Mr. Murdoch instanced the well-known case of Betts *v.* Menzies in illustration of this part of his argument. In this case it was contended that Betts's patent was bad because the invention it protected was described in the specification of a prior patent, and it was not till the case had gone from court to court that Betts's patent was decided to be good. Now, all this litigation arose from the similarity of Betts's and Dobbs's specifications, which was such, that if Betts, in order to obtain his patent, had been required to submit a description of his invention for preliminary examination, the patent would, in all probability, have been refused, on the ground that his invention had been anticipated by Dobbs; and although the practical difference between the two inventions was exactly that between success and failure, he would have been deprived of his reward. This was but one of many cases which might be cited, to show the injustice which would be inflicted upon inventors, and the loss which would be sustained by society, if the novelty or merit of an invention were to be investigated before the grant of the patent, although he was willing to admit that, in some cases, the difficulties which he had suggested would be met by the plan proposed by Mr. Wilson, which he took to be this—that the usual provisional protection (six months) should be issued, but that the novelty and utility of the invention should be inquired into previously to the sealing of the patent. There were cases, however, in which years elapsed before the invention was brought into satisfactory operation, and to such cases Mr. Wilson's proposition would not apply. It had been said that the action of the preliminary tribunal would be analogous to that of the Privy Council in prolongation cases. There would, however, be this difference—the examiners would have to decide on such evidence as might be collected during a period of a few months, whereas the Privy Council based its decisions on evidence that had been accumulating during the whole term of a patent. He did not think, however, that we need trouble ourselves to devise any system of preliminary examination, as the part of our patent system requiring reform was, not the mode of granting patents, but the mode of trying patent cases. The trial of a patent case was now so tedious, so expensive, and so uncertain, that men would often suffer wrong rather than go to law to obtain redress. The consequence of this state of things was, that inventors often took out patents without making due inquiry respecting the novelty of their inventions, and filed vague specifications, relying on the reluctance of others to contest their claims in a court of law, whilst, on the other hand, patents were often infringed by manufacturers and others, who hoped to wear out the patentees by the help of a long purse. In both cases capital became but too frequently a means of oppression. There were provisions of the present law which, if they could be readily and effectively administered, would be amply sufficient to meet such cases. There were remedies of the patentee against the public, and *vice versa*. The difficulty was that in applying these remedies the whole case turned upon the construction of the specification, which was a duty to which our courts, as at present constituted, seemed to be unequal. The remedy was to be found in the strengthening of the court, as set forth in Mr. Webster's second proposition, viz., "That the validity and infringement of patents should be tried by a judge, assisted by two or more assessors, conversant with the subject." He thought it would be very advantageous to extend the functions of this court to the granting and extension of patents. The court would then perform the duties which were now performed by the law officers, our courts of law, and the Privy Council. The advantages of this arrangement would be that those who examined applications for patents would not go out of office with each change of ministry, by which system their experience in matters of patent practice was at present lost to the public, and the court would be fully acquainted with the history of each patent granted.

Mr. G. W. Hastings had listened with interest to the opinions that had been advanced on this subject by practical men who had taken part in the discussion. He confessed, as far as he was personally concerned, he had no other pretension to speak upon the matter beyond that of strict impartiality. He had no personal interest in it whatever, and he simply represented the interest which after all would have to finally settle this great question—that was the interest of the public. He thought it rather unfortunate that one or two of the speakers had, probably in the heat of argument, thrown some doubt on the right of the public to have any interest in the question. Now he had every respect for the interests of patentees, but he thought the public had a right to be heard in the matter. It seemed to have been assumed by the gentleman (Mr. Spencer) who on the last occasion spoke in reply to the very admirable speech of Mr. Hawes, that if they once conceded that there was a property in invention, they at once settled the whole question, and that therefore the present patent law was always to be maintained. He begged to deny in the most explicit manner the force of that argument. He was fully impressed with the feeling that there was a property in invention, and that that property ought to be maintained. He thought when a great inventor gave to this country the benefit of some discovery, he was deserving of very high reward, and his merits ought to be recognised; but he did not see, while acknowledging that, that there

was any necessity to maintain the present or any patent law at all. Let them go for a moment into this question. The gentleman who opened the discussion this evening told them that the patent law and the copyright law stood on precisely the same grounds. Now, he (Mr. Hastings) could hardly imagine two things more diverse, and it was from that misapprehension partly that so many errors had crept into the subject. He would give them an instance of the difference between copyright and patent law. When Sir Walter Scott wrote his "Waverley," he introduced into this country an entirely new species of literature—historical romance—and he obtained the copyright of that work, and it would have been piracy to have reprinted it *ipsissimis verbis*; but they did not by that grant to Sir Walter Scott a monopoly in the printing of historical romances. They did not say that for a certain number of years he should be the only person in this country to produce novels of that description. They allowed any one who chose to write historical romances; but the principle of the patent law was that they should confer upon one man who had invented a particular thing an absolute monopoly in it. The point he arrived at was this: granting there was a property in invention, was the present system of patent law the best system for securing that property either as regarded the inventor or the public? He would deal with the question first as regarded the public. In ancient times it was considered that if an enterprising navigator discovered a new country, the only proper way to reward him was to make him a grant of that country; but in process of time it was discovered that the better plan of reward was to give a suitable recognition of the discovery, and throw the land open to public use and occupation. Much the same question was involved in the patent law—whether there was not a better way of rewarding than giving a monopoly? The argument on public grounds had been that by granting patents they encouraged invention. But what did one speaker say? That under any circumstances they would have invention—that invention, once in the head, it must come out. He quite subscribed to that. He believed the faculty of invention was like the faculty of poetry, or of art, and if a man had that genius within him he was sure to invent. If that were true, as the gentlemen in favour of the patent law had informed them, it seemed that the case of the patent law, as far as the public was concerned, fell to the ground; for it was clear the public had the benefit of the invention whether they rewarded the inventor or not. In that case every shilling paid in fees to the patent office was so much useless burden upon the public, for, after all, it came out of the public purse. It seemed to him, as far as the public was concerned, the patent law, on its present footing, was wholly indefensible. He would now consider the question from the inventors' point of view. Was the granting of a monopoly the best means of rewarding him? If there was any truth in the facts and figures of Mr. Hawes, it seemed a bad way of rewarding him. It seemed to create a lottery in which very often the best man lost and the worst man won. It seemed a mode of rewarding which might not only fail in its object, but might lead the unfortunate inventor to spend his whole life in an idle pursuit of riches. He thought, as far as the inventor was concerned, a more satisfactory plan would be that each invention should be valued by a competent tribunal, and that it should be rewarded by a certain sum at once from a public fund, upon its being declared to be a true and really good invention. That would surely be a more certain and, he apprehended, a more satisfactory plan than the present system of patents, and he thought this the more because he could not help feeling how inadequate had often been the rewards to really great inventors of this country under the present law. Large fortunes had often been made by men whom it would be ridiculous to term inventors—men who had made some trifling modifications, while those who had conferred illimitable advantages not only on this country but on the world, had sometimes been left to die in poverty. He trusted he had demonstrated first, that the present system was not satisfactory to the public, and secondly, that it was not so to inventors. If that were the case, he thought the legislature of this country, enlightened by the assistance of this Society, should take the matter into consideration, and enact for the benefit of inventors, as well as the community, a system which would be satisfactory to both, which would give the best reward to genius, and would not deprive the public at large of the free use of the invention.

(To be continued.)

CORRESPONDENCE.

THE BONELLI TELEGRAPH COMPANY.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—Your correspondent, — — - - —, forgot to mention in his letter that the only interruption in the working of the wires of the above company was owing to an accident to the aerial cable across the Mersey at Runcorn, the injury being caused by the mast of a ship.

Yours, &c., A FACT.

COLONIAL TELEGRAPHY.

THE following particulars of the telegraph in Victoria, is supplied by the *Weekly British Colonist*:—

The Act empowering the California State Telegraph Company to lay down a line of telegraph wires into this colony, which has now become law, is likely to work changes in our city in many respects. In the first place, it must of necessity work a revolution in mercantile affairs. There is not one of our Wharf-street merchants and not one of our Fort-street retail storekeepers but will feel the difference which telegraphic communication will make in their business. There are some who still hold to the exploded slow-coach system, and imagine that nothing can be done better because it is done more quickly than of yore, but in a city so dependent upon trade alone as is Victoria, the benefit of having immediate intelligence of the state of the markets in San Francisco and the Eastern States, and of our merchants being enabled to execute orders promptly from California markets, will rapidly make itself felt amongst us. To newsmongers the assistance of the wire will doubtless be very great, although it will rob our news of that interest which it has on the arrival of the mails by partially anticipating the items; but nevertheless we would fain hope that it will in some measure enliven us and render the contents of the columns of the daily journals more acceptable to our readers than at present. It is probably owing to a dearth of real news that some are occasionally betrayed into the grave error of abusing one another, and running down the prospects of the colony and city, which it is, unquestionably, our great interest to uphold.

The following are the provisions for the regulation of the telegraphic business of the colony.

Section 1, providing that employés or others may not divulge contents of messages nor alter the meaning of the same under a penalty not exceeding $1,000, or imprisonment for one year, was passed.

Section 2, providing that no forged messages be sent under a penalty not exceeding $1,000, or imprisonment for one year, was passed.

Section 3, providing that no employé shall appropriate any information under a penalty of $1,000, or one years' imprisonment, was passed.

Section 4, providing that no employé shall neglect to send messages under a penalty of $500, or six months' imprisonment, was passed.

Section 5, providing that unauthorized persons may not violate sealed messages, under a penalty of $1,000, or one year's imprisonment, was passed.

Section 6, providing that persons not employés may not fraudulently obtain any telegraphic information, under a penalty of $1,000, or one year's imprisonment, was passed.

Section 7, providing that no person may attempt to procure information by bribery, under a penalty of $1,000, or one year's imprisonment, was passed.

Section 8, providing that if any person shall wilfully obstruct or injure any telegraph lines or submarine cable, they shall be liable to a penalty of $500, or six months' imprisonment, was passed.

Section 9, providing for civil action for damages, was passed.

Section 10, exempting employés from militia and jury duty, was passed.

Section 11, providing that contracts made by telegraph shall be deemed contracts by writing, was passed.

Section 12, providing that notices served by telegraph may be deemed actual notices, was passed.

Section 13, providing that grants and conveyances may be made by telegraph, was struck out.

Section 14, providing that checks, due bills, promissory notes, bills of exchange, &c., may be made by telegraph, was passed.

Section 15, providing that certified instruments may be sent by telegraph, and shall *prima facie* be deemed genuine, was struck out.

Section 16, providing that arrests may be made by telegraph, was passed.

Section 17, providing that notes or orders may be sent by telegraph, was passed.

Section 18, providing that in any document sent by telegraph bearing a seal, the seal may be expressed by the letters "L. S.," or the word "seal," was passed.

Section 19, providing that any device adopted by the company may be made copyright, was passed; any person unlawfully using the same being liable to a penalty of $500, or six months' imprisonment.

Section 20, defining the construction of certain terms in the bill, was struck out.

Section 21, providing that telegraphic messages must be sent in order as received, under a penalty of $500, provided that official despatches, or those of a public or general interest, shall be transmitted out of their order, was passed

Section 22, conferring jurisdiction on justices of the peace to try any misdemeanour created under this act was passed.

The committee rose and reported the passage of the bill.

TELEGRAPHIC NEWS.

The Electric and International Dramatic Club.—The fifth entertainment of the above Society will be given at the Cabinet Theatre, Liverpool-street, King's-cross, on Thursday the 26th inst. The programme includes a comic drama, in two acts, by Messrs. Thos. and J. W. Morton, entitled, "All that Glitters is not Gold;" a domestic drama, in two acts, by Edward Fitzball, Esq., entitled, "The Momentous Question;" and other diversities.

Canadian Telegraph Company.—A new company has been organised in Canada, called the Provincial Telegraph Company, with which the United States Company will be connected at Suspension Bridge and Montreal. One of the most important features of this enterprise is its probable connection with a line to Europe, to which the attention of the public has not been called. This line is from the coast of Labrador, viâ Greenland, Iceland, and the Faroe Isles, to the north shore of Scotland. The longest distance from shore to shore is less than 500 miles—a less distance than cables are now successfully working in the Mediterranean.

Persian Gulf Telegraph.—The following telegram has been received from Col. Stewart, dated 30th March:—"Copper wire of cable parted about 90 miles from Fas at noon yesterday. This can certainly be made good in a few days. In meantime cable will be landed at Fas, and connection completed. Land line completed from Fas, 100 miles north of Kurnah; and from Bagdad 100 miles south; intermediate portion, 170 miles in length, passes through a country of Montific Arabs, at present in rebellion against the Turkish Government. Good reason to believe that differences will be immediately adjusted, and work recommenced; but for the present no certain means of communication with Bagdad except by river steamer."

A New Project.—The Floating Telegraph Station and Light-Ship Company has been announced, with a capital of £250,000, in shares of £10 each. The object is to provide and anchor ships near the ordinary track of vessels, in order to serve as electric telegraph and signal stations in communication with existing systems in Europe and America, and also as safety beacons for navigation. The first stations selected by this company for regular service are off the Scilly Islands, at the entrance of the English and Irish Channels, and off Cape Race, Newfoundland. The engineers and electricians to this company are Messrs. Forde and Fleeming Jenkin; and the board includes the names of several gentlemen well known in the commercial world.

MISCELLANEA.

Matter and Vacuum.—A pure vacuum is space void of all matter. Were all matter out of the universe, nature would then be nothing but a pure vacuum, and this pure vacuum would have some kind of an aspect. This aspect would be something similar in quality to the zigzag light which is formed when concentrated electricity suddenly divides the air, as when it lightens. Could a certain amount of space be freed of all matter, say a cubic mile, the freed space would have an appearance similar to the vacuum caused by concentrated electricity dividing the air, as when it lightens.

Process for Bleaching Gutta-Percha.—The *Journal de Pharmacie* gives the following process for bleaching gutta-percha:—"Dissolve the gutta-percha in twenty times its weight of boiling benzole, add to the solution plaster of very good quality, and agitate the mixture from time to time. By reposing for two days the plaster is deposited, and carries down with it all the impurities of the gutta-percha, insoluble in benzole. The clear liquid, decanted, is introduced by small portions at a time into twice its volume of alcohol, 90 per cent., agitating continually. During this operation the gutta-percha is precipitated in the state of a pasty mass, perfectly white. The dessication of the gutta-percha, thus purified, requires several weeks' exposure to the air, but may be accelerated by trituration in a mortar, which liberates moisture which it tends to retain."

Residual Magnetism.—Dr. A. Van Waltenhofen asserts that the amount of magnetism remaining in the soft iron of an electro-magnet, after the cessation of the electric current, is dependent on the manner in which the current is interrupted. The amount is greater after a gradual interruption. The residual magnetism in very soft iron is often of an opposite nature to that previously existing, after the very sudden interruption of a strong current. This seems to him to furnish strong proof that magnetism is not caused by the separation of two fluids, but by the motion of magnetic molecules to which is opposed a certain amount of frictional resistance. He compared each magnetic molecule to a spring which is bent back. If suddenly released it will return to its original position or go beyond it, but if gradual released it will not go quite to its primitive place.

Pure Copper Paint.—A new pigment, calculated at the same time to increase the resources of the decorative painter, and to afford a ready means of preserving iron and other metals, has recently been introduced at Paris by M. L. Oudry, of the Auteuil Electro-Metallurgic Works. He first obtains a pure copper by throwing down the metal by the galvanic process; he then reduces the precipitate to an impalpable powder by stamping. This powder is then combined with a particular preparation of benzine, and used in the same way as ordinary paint; beautiful bronzed effects are produced upon it by means of dressing with acidified solutions and pure copper powder. The articles painted with the new material have all the appearance of electro-bronze, whilst its cost is less than one-sixth; it will last from eight to ten years. Mr. Oudry also proposes to substitute benzine oil for linseed and other oils, over which he states it possesses great advantages.

Coast Signals.—Some public-spirited individual writes the appended letter to the Stoughton (Mass.) *Sentinel*. Apparatus similar to that mentioned by the writer alluded to is now in use; but he advances some original ideas which are worthy of attention:—"Having been impressed with the idea that some kind of a trumpet or whistle might be made that would be very useful to give warning to seamen when located on dangerous rocks and shoals, to ease my mind I have concluded to give some of my ideas for you to dispose of as you may think proper. The trumpet for this purpose should be like the common ones, except in size, with a shell attached to the mouth-piece like a small egg-shell, with a whistle or reeds, as scientific men versed in such instruments may determine, with another larger shell over it, with space between sufficient to blow through. I should think when blown this would be a sufficient warning in fogs. Not knowing what sounds are produced by the wind, rigging, and waves, I suggest none, for I never heard them. Some of the methods of blowing are by a pipe (the right length and dimensions of which would depend on the size of the boat to which it was attached), to rise and fall perpendicularly in the water with the motion of the boat, with a tube leading from the pipe to a trumpet. Any one wishing may see the principle on which it works by taking a keg, knocking out one head, bore a hole in the other, and passing it up and down perpendicularly in the water. Another way may be possible by a ball fitted inside of a tube to roll back and forth by the motion of the boat, with valves inhaling and exhaling, as the case may be, and tubes leading to the trumpet. Possibly weights might be suspended so as to swing and blow a bellows, or perhaps weights to run on a trundle to be passed back and forth by the motion of the boat, with a rod entering one end of a tube and a piston on the end to pass back and forth in the room of a ball; or perhaps the waves, in passing a boat, might turn side wheels and blow a bellows. May not such a one be sufficient for calms, and cannot one be blown in storms by wind? and may not the sound be increased by the bigness of the trumpet and the number of whistles blown in it? Now, cannot some of your readers study out and put in operation an invention of this character which will be of so much value to seafaring men?"

Diseases of Overworked Men.—Time was when the very phrase, diseases of overworked men, would have been considered foolish, and out of the question; now it conveys a truth of national importance, which the nation must consider. From being a comparatively idle world, we have, of late, become an insane world on the subject of labour. So long as the muscles merely were employed, so long little harm was done; we remained men; now we aspire to be gods, and we pay the forfeit of our ambition. From overwork we now get a class of diseases the most prolonged, the most fatal. The suns of our best men go down at noon, and so accustomed are we to the phenomenon that we cease to regard it as either strange, or out of place. It is through the mind now that the body is destroyed by overwork; at all events, it is so mainly. The men of intense thought—men of letters, men of business who think and speculate, men of the state who are ambitious to rule, these men are sacrifices. With them the brain has not merely to act on its own muscles, bidding them perform their necessary duties, but the one brain must needs guide a hundred other brains, and all the muscles thereto appended. An electric battery works a single wire from the City to Brighton, and does its work well, and goes on for some months before it is dead or worn out. Can it do the work of a hundred wires? Oh yes, it can, but it must have more acid, must wear faster, and will ultimately die sooner. We may protect the plates, make the battery, to an extent, self-regenerative as the body is, but, in the main, the waste is in excess of the supply, and the wear is as certain as the day. Men of letters, men of business who do their business through other hands and do great business, and men immersed in politics, suffer much the same kind of effects from overwork. They induce in themselves, usually, when they suffer from this cause, one or other of the following maladies:—Cardiac melancholy, or broken heart; dyspepsia, accompanied with great loss of phosphorus from the body; diabetes, consumption, paralysis, local and general; apoplexy, insanity, premature old age. They also suffer more than other men from the effects of ordinary disorders. They bear pain indifferently, can tolerate no lowering measures, are left long prostrated by simple depressing maladies, and acquire, in some instances, a morbid sensibility which is reflected in every direction; so that briskness of action becomes irritability, and quiet, seclusion and moroseness. They dislike themselves, and feel that they must be disliked, and if they attempt to be joyous, they lapse into shame at having dissembled, and fall again into gloom.—*Social Science Review*.

THUNDER-STORMS.—Storms of thunder and lightning are simply a case of electrical discharges from one cloud to another, and are a means adopted by nature to restore electrical equilibrium in the atmosphere, and at the same time clear the air from unwholesome vapours or properties. The explanation of thunder-storms given by Professor Thomson, in his "Outlines of the Science of Heat and Electricity," being the best we have seen, we shall lay it before the readers:—"Air and all gases are non-conductors; but vapour and clouds, which are composed of it, are conductors. Clouds consist of a kind of bladders of vapour, charged each with the same kind of electricity. It is this electric charge which prevents the vesicles from uniting together, and falling down in the form of rain. Even the vesicular form which the vapour assumes is probably owing to the particles being charged with electricity. The mutual repulsion of the electric particles may be considered as sufficient (since they are prevented from leaving the vesicle by the action of the surrounding air and of the surrounding vesicles) to give the vapour the vesicular form. In what way these clouds come to be charged with electricity, it is not easy to say. But, as electricity is evolved during the act of evaporation, the probability is that clouds are always charged with electricity, and that they owe their existence, or at least their form, to that fluid. It is very probable that when two currents of dry air are moving different ways, the friction of the two surfaces may evolve electricity. Should these currents be of different temperatures, a portion of the vapour which they always contain will be deposited; the electricity evolved will be taken up by that vapour, and will cause it to assume the vesicular state, constituting a cloud. Thus we can see, in general, how clouds come to be formed, and how they contain electricity. This electricity may be either vitreous or resinous, according to circumstances. And it is conceivable that, by long-continued opposite currents of air, the charge accumulated in a cloud may be considerable. Now, when two clouds, charged, the one with vitreous and the other with resinous electricity, happen to approach within a certain distance, the thickness of the coating of electricity increases on the two sides of the clouds which are nearest each other. This accumulation of thickness soon becomes so great as to overcome the pressure of the atmosphere, and a discharge takes place which occasions the flash of lightning. The noise accompanying the discharge constitutes the thunder-clap, the long continuance of which partly depends on the reverberations from neighbouring objects. It is, therefore, loudest and largest, and most tremendous in hilly countries. These electrical discharges obviously dissipate the electricity; the cloud condenses into water, and occasions the sudden and heavy rain which always terminates a thunder-storm. The previous motions of the clouds, which act like electrometers, indicate the electrical state of different parts of the atmosphere. Thunder, then, only takes place when the different strata of air are in different electrical states. The clouds interposed between these strata are also electrical, and owe their vesicular nature to that electricity. They are also conductors. Hence they interpose themselves between strata in different states, and arrange themselves in such a manner as to occasion the mutual discharge of the strata in opposite states. The equilibrium is restored; the clouds, deprived of their electricity, collapse into rain, and the thunder terminates. In thunder-storms the discharges usually take place between two strata of air, very seldom between the air and the earth. But that they are sometimes also between clouds and the earth cannot be doubted. These discharges sometimes take place without any noise. In that case, the flashes are very bright; but they are single flashes, passing visibly from one cloud to another, and confined usually to a single quarter of the heavens. When they are accompanied by the noise which we call *thunder*, a number of simultaneous flashes of different colours, and constituting an interrupted zigzag line, may generally be observed stretching to an extent of several miles. These seem to be occasioned by a number of successive or almost simultaneous discharges from one cloud to another, these intermediate clouds serving as intermediate conductors, or stepping-stones, for the electrical fluid. It is these simultaneous discharges which occasion the rattling noise which we call thunder. Though they are all made at the same time, yet, as their distances are different, they only reach our ear in succession, and thus occasion the lengthened rumbling noise, so different from the snap which accompanies the discharge of a Leyden jar. If the electricity were confined to the clouds, a single discharge, or a single flash of lightning would restore the equilibrium. The cloud would collapse and discharge itself in rain, and the serenity of the heavens would be restored; but this is seldom the case. I have witnessed the most vivid discharges of lightning from one cloud to another, which enlightened the whole horizon, continue for several hours, and amounting to a very considerable number, not fewer certainly than fifty, and terminating at last in a violent thunder-storm. We see that these discharges, though the quantity of electricity must have been immense, did not restore the equilibrium. It is obvious from this that not only the clouds, but the strata of air themselves, must have been strongly charged with electricity. The clouds, being conductors, served the purpose of discharging the electricity with which they were loaded, when they came within the striking distance. But the electric stratum of air with which the cloud was in contact, being a non-conductor, would not lose its electricity by the discharge of the cloud. It would immediately supply the cloud with which it was in contact with a new charge. And this repeated charging and discharging process would continue to go on till the different strata of excited air were brought to their natural state."—*Chambers.*

PATENTS.

LETTERS PATENT.

2893. J. G. Jennings, and M. L. J. Lavater, improvements in the manufacture of tubes, rings, and cords of india-rubber, and in covering telegraph wires.

2962. C. L. Daboll, improvements in fog-signals or alarums.

PROVISIONAL PATENT.

999. H. H. Bonneville, a new method of obtaining a semi-fluid or solid product obtained by concentrating the saponaceous parts of the qualli tree.

TO CORRESPONDENTS.

As information respecting Improvements, Extension of Lines, and Progress of New Undertakings will at all times be most acceptable, we hope that our readers will kindly render us assistance in our efforts to establish a Journal worthy in all respects of the great interest it seeks to represent, by furnishing us with brief notices of events and occurrences in connection with Telegraphy.

Communications intended for publication must be authenticated by the names and addresses of the writers; not neccessarily for insertion.

Letters relating to Advertisements are to be addressed to the Publishers. All other letters and communications to be addressed to the Editor of the *Telegraphic Journal*, 5, Suffolk-lane, Cannon-street, London, E.C.

The *Telegraphic Journal* can be had of Messrs. SMITH & Co., Strand; Messrs. DAWSON & Co., Cannon-street, E.C.; Messrs. KENT & Co., Paternoster-row, London. Messrs. HEYWOOD & Co., Manchester; at the various railway stations; and of all news-agents, &c., &c.; or it can be supplied, if preferred, direct from the Office on the following terms:—

	s.	d.
Quarterly	4	4
Half-yearly	8	8
Yearly	17	4

TO ADVERTISERS.

The *Telegraphic Journal* is the most effective medium for inventors, patentees, contractors, manufacturers of insulating materials and electrical apparatus to submit their various specialities to the consideration of secretaries and managers of telegraph or railway companies, and other persons engaged in electrical and telegraphic pursuits.

Clerks, assistants, manipulators, and instrument makers, seeking employment, &c., will find the *Telegraphic Journal* a ready means of making known their requirements.

Advertisements must be delivered to ensure insertion before SEVEN O'CLOCK on Thursday evening in each week. The charges for Advertisements are—

	£.	s.	d.
Whole page	4	4	0
Half ditto	2	10	0
Quarter ditto	1	7	6
Four lines and under (single column)	0	3	0

Single Advertisements from the country must be accompanied with stamps in payment.

THE CONSTRUCTION OF TELEGRAPHS.

(*Continued from page* 242.)

At every terminal station especially a very important matter is the "earth." This should receive the most strict attention. Too much care cannot be taken to secure a good one. The method usually adopted to test an earth-wire is to send a current in one wire, placing a sensitive galvanometer in circuit on the shortest of the others—one erected on separate poles, if possible. If no current passes through the galvanometer the earth is perfect. A bad earth will not only increase the resistance of a circuit, rendering the signals weak, but where more than one wire is in connection with it, will form a contact; for it is evident that the charge being rejected by the earth wire, in consequence of the non-conductive powers of the soil, it will return and traverse that other wire affording it least resistance, till it has completed its circuit. A water or gas-pipe is preferable to an earth-plate from the larger surface it affords. Care must be taken to make the connection with the main street gas-pipe, as the joints of indoor gas-pipes are frequently packed with white or red lead. A case is recorded where an earth-wire, which was connected to a small leaden gas-pipe, in use at the time, when a strong flash of lightning passed along the wire, and, consequently, into the earth-wire. The connection was, probably, not a good one, for the pipe was melted at the point of contact, and the gas ignited, causing considerable danger to property. This is another objection to the use of indoor gas-pipes.

When neither water nor gas-pipes are obtainable, an earth may be formed as follows:—Select a spot, where by digging to a reasonable depth—say 6 or 8 feet—you may find soil wet at all seasons. Form a narrow trench, in which lay your earth-plate, composed of a strip of lead not less than 4 feet by 2. Do not coil it, but let it be buried flat and upright, rather than horizontal. To this connect your earth-wire, and fill in the trench with coke.

It sometimes happens that an *earth* cannot be found. This is frequently the case in chalky ground, or where the soil is constantly dry. The evil may, perhaps, be overcome by employing a separate earth-plate for each circuit, maintaining them at such a distance apart that the resistance of the soil, between the plates, shall be greater than the resistance of the earth to the diffusion of the tensions. If this fail, we have but one alternative, viz., to carry a wire along the poles till we come to a spot capable of affording a good earth.

Mr. Culley, in his "Handbook," previously referred to, quotes the following interesting results obtained by Matteuci; the size of the earth-plates being the same in each case:—

	Resistance.	Resistance.
Plates 1 yard apart on the level plain,	68, on a mountain,	152.
" 5 " "	97, "	—
" 10 " "	102, "	222.
" 20 " "	109, "	—
" 50 " "	123, "	531.
" 100 " "	—	809.

The resistance diminishes with the depth to which the plates are buried.

When buried 4 inches the resistance was	91.
" 10 " "	83.
" 40 " "	74.
" 80 " "	70.

The size of the plates has the greatest influence on the resistance.

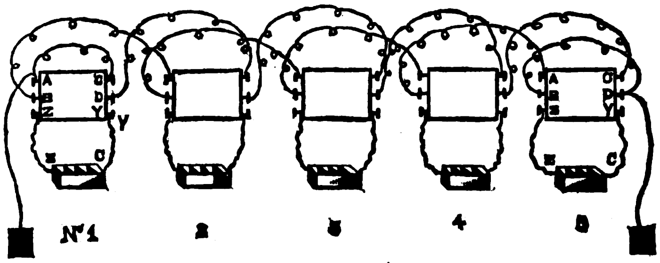
If a plate containing 1 square foot of surface gives a resistance of 174,

A plate of 4 square feet will give a resistance of	140.
" 16 " "	81.
" 25 " "	47.
" 32 " "	31.

But after a certain size, varying with the conductive power of the soil around the plates, the resistance remains constant.

It sometimes happens that very short circuits are troubled with a permanent, though perhaps not a very strong current, constantly deflecting the needle to one side. You may safely attribute this to the earth-plates. An iron earth-plate at one end, and a copper or lead one at the other, will form a battery, and emit the current observed. Thus the necessity of having both earths similar, or as nearly so as possible.

The following sketch will enable the student the more easily to follow up the various connections.



Having gone through the important question of "earth," we may now commence joining up our instruments. To our old and esteemed friend, the double-needle, we give the precedence. Each terminal is marked generally as shown in the figure. A, B, and Z, on the left hand side, C, D, and Y, on the right. A, B, C, and D, are the line terminals, Z and Y, battery terminals. A and B communicate with the + E needle, whilst C and D form a circuit with the H N. With the battery terminals we cannot well make a mistake, there are but two, both marked. Should they, however, not be marked, take a note, that zinc is connected to the left hand terminal, and copper to the right. With the other four terminals we shall be apt to err, unless we bear in mind which is the up and which the down, that through which the current enters the instrument, and that by which it leaves it. Method is the soul of success. Let it then be determined that A and C shall bear the up wires, and B and D the down wires. Unless we start with some such arrangement, we shall probably confuse our wires and connect our instruments up wrongly. If we cross the wires, that is connect the + E wire to B, instead of to A, and the down wire to A, the signals made by that instrument will appear correct, but will be reversed at all other stations. Signals sent by any other station will also be reversed to you. By altering the wires of the H N, we meet with a similar result. To change the battery wires would reverse all signals made by you, not only at your own station, but throughout the circuit. We here surmise that all the leading-in wires have been duly marked as they should be, at the time they are laid in, in accordance with the wires as they stand on the poles. The circuits are arranged as follows:—Nos. 1, 2, and 3, are devoted to the train signals; No. 4, to the printing circuit; Nos. 5 and 6, double-needle. The object in thus selecting them is, as will be inferred, that we may devote those wires least likely to meet with interruption to the most important circuits. The top wire will not, of course, be liable to so many interruptions from contact as the lower wires, for although every possible precaution is adopted, yet a wire will occasionally snap from a bad weld, or an insulator will give way, and many other accidents occur, unlooked for till they actually take place.

Selecting No. 5 line wire we connect it to the instrument at A; No. 6 to C; and B and D, having to be put to earth, we connect our earth to the latter, and, leading a wire thence, join it to B. Thus the current enters at A, passes through the + E coil, thence into the spring, and away through B, into the earth. With the H N, it follows a similar course, entering at C, and leaving by D.

We may now pass on to Nos. 4, 3, and 2 stations. Here the connections are all the same, except that instead of connecting up the earth to B and D, we join up the down line wires. Arrived at No. 1, we have but to repeat the care and attention bestowed upon No. 5, look to the earth, and connect up the batteries and line wires. Here we find the earth wires connected to A and C, B and D being occupied by the down wires.

FLOATING TELEGRAPH STATION AND LIGHT-SHIP COMPANY, LIMITED.

A very laudable project has been launched, and, we hear, rapidly approaches realization—if a kindly reception in the money market augurs any good. The objects proposed to be encompassed by the Floating Telegraph Station and Light-ship Company, Limited, commend themselves to the mercantile and marine interests of the country as of vital importance. Any scheme which is calculated to either protect our commerce, or expedite our communication with friendly countries, separated by vast oceans or solitary wildernesses, will never fail to receive support; for a nation that turns over in its trade the sum of £1,500,000 with every setting of the sun, or an amount equal to, if not exceeding, £547,000,000 sterling annually, needs every application of science and art to aid in the development of its illimitable resources. The genius of our inventors is readily met by the spirit of enterprise in our capitalists, and we have now to chronicle the application of an useful invention to one of the most important undertakings of the present age. The aforesaid company will provide and anchor ships near the ordinary track of vessels trading between Europe and America and elsewhere—said vessels to serve as telegraph and signal stations, and also as beacons for navigation. The method by which the company purpose to carry out its plans has not transpired, but we have reason to believe that it is in contemplation to purchase Moore's patent for an improved method of anchoring ships, and attaching electric cables. By this invention it is alleged that a vessel can be moored amid the wild waves of the Atlantic, and can secure easy communication with passing ships and with the shore. The stations selected for the first operations of the company are off the Scilly Islands, the entrance to the English and Irish Channels, and off Cape Race, Newfoundland. These positions recommend themselves as eligible depôts, for about 100,000 vessels pass Scilly and 3,500 pass Cape Race annually. Moreover, the frequent opportunity for performing salvage services, and the eagerness with which navigators seek to obtain these points of departure for entering the English and Irish Channels and the Gulf of St. Lawrence respectively, considerably enhance the importance of the project, which certainly promises to be exceedingly profitable.

This company's ships will be fitted up complete as telegraph stations. It is also intended to provide them with steam power and lanterns for displaying a powerful light. Day and night signals, steam whistles, guns, lifeboats, &c., will also form part of their equipment. Stores, water, and provisions will be kept on board for the immediate requirement of vessels in distress; a further supply, including coals, will be kept on shore, always available at a few hours' notice.

Steam-tenders, fitted up for the conveyance of passengers, mails, specie, and merchandise, and capable of acting as tugs, will be provided by the company, so that assistance can be rendered to disabled or derelict vessels.

At the station at the entrance of the English Channel all vessels arriving from India, China, North and South America, the Cape of Good Hope, West Indies, and all parts of the world, whether bound for England or the Continent, will exchange news and communicate arrival from one day to a week before reaching port; and those outward bound will receive news and instructions so much later. The advantage gained in point of time between Cape Race and New York will vary from *four days* for steamers to *a fortnight* for sailing vessels. The importance to trade of these facilities can hardly be estimated, but an idea may be formed of the profits likely to be realised, when it is stated that if but one vessel in three sent only a single message, the profits would, at £1 per message, pay nearly 15 per cent. upon the capital. It is expected that most ships will telegraph their numbers on arrival and departure, and that off Scilly a large number of those arriving will call for final orders of destination, whilst the English, Irish, and Bristol Channels are still open to them. It is understood that even now, when the uncertainty of delivery keeps the number of messages at a minimum, numerous telegrams for the United States and Canada are conveyed by each mail steamer, to be landed, if possible, at Cape Race. The steamers are only occasionally intercepted in fine clear weather by a sailing boat belonging to the Associated Press. The charge for landing is at the present time over £2 per message.

This project recommends itself, not only in its commercial aspect, but as tending to diminish the destruction of life and property, as it will enable vessels to ascertain their position by light-ships at sea, thus avoiding the necessity of a near approach to the shore, and enabling them to proceed on their course with confidence and safety.

The main source of revenue is expected to arise from telegrams, as the company's line will connect the Scilly Islands with the European telegraphic system. In addition, it is believed that the profits to be derived from salvage, the sale of stores, and the embarking and disembarking of mails, parcels, and passengers, will prove eminently remunerative, while the saving of human life from shipwreck off dangerous coasts is a consideration which will doubtless induce many to embark in this enterprise uninfluenced by the attractions of large returns for capital invested.

A SPECIAL LINE FOR URGENT MESSAGES.

Within the past few years many improvements have been effected in the administration of telegraph companies. The tariffs for the transmission of messages have been considerably reduced; additional stations have been opened wherever a prospective business could be anticipated, and the greatest facilities have been offered the public for communication by the telegraph. But there is still a deficiency in the system which might be provided against without material interference with existing arrangements. The practice of sending telegrams without distinction as to character, on the principle of "First come, first served," is fraught with many disadvantages which have been very forcibly pointed out by our contemporary, *The Realm*:—

"The invention which especially distinguishes the advanced science of the day, and which has introduced a new element into politics, and even war, is the electric telegraph. Telegraphic communications are at present carried on by private enterprise, and though Government can, and has, on great and critical occasions, monopolised them for a time, the companies alone are responsible for the orderly and accurate transmission of information, both public and private, demanding unusual dispatch. Important as are the public functions of telegraphic companies, they owe their origin to, and derive their chief support from, the public's private and personal requirements. The importance of these communications varies infinitely, from cases in which dispatch or delay means life or death, down to a telegram for a night-cap and tooth-brush. The

present rule, if rule there be, seems to be the transmission of messages in the order of their arrival at the office, irrespective of their relative importance—the price of strawberries and young potatoes in the Bath market, taking possible precedence of a summons to a death-bed, or the few words which would relieve agonies of anxiety and suspense.

"Government has not hesitated to interfere with private companies in the case of railways, forcing them to run a certain number of trains at a low rate of payment to benefit the poorer classes of society, whether remunerative to the companies or not; why should it not interfere so as to place the telegraphs under some systematic and efficient regulation? Our attention has been drawn to this subject, which involves a great evil, one demanding an immediate remedy, if the telegraph is to be in fact, that which it professes and is generally supposed to be, a means of instantaneous communication in cases of difficulty.

"Instances of failure in this respect will occur to too many of our readers. We will give an instance. In a recent case a message from the south of Europe requiring the immediate presence of a near relative, arrived at a country town in England in twelve hours —as rapidly, in fact, as could be expected. The terms of the message were urgent, 'start instantly.' A man was sent to *walk* the remaining eighteen miles, to bring it to its destination, and, in consequence, the first train and the first packet over the water were missed, the telegram itself being so mis-spelt as to make the route intended to be indicated, incomprehensible! Mere carelessness! In a copy of this telegram forwarded the next day, too late to be of use, the words were correctly spelt. What excuse can be offered for such slovenly work as this?

"Again, an urgent telegram most anxiously expected, arrived in London late on Saturday night. The office was closed. That message was detained till Monday morning. A message respecting a little dog, and another asking some children to a dance, were forwarded by a mounted messenger post-haste. Discretionary power is open to bribery; but these companies who are paying large dividends derived from the confidence of the country in the effectual performance of the functions they profess, should have some systematic classification by which urgency can be tested if only by the rough proportion of money to speed. Some provision might be made at exceptional rates for nights and Sundays. And the high-rate messages should be backed with some recoverable damages for neglect, so as to enforce the terms of special contract as to guaranteed dispatch. As it is, the companies shift responsibility from one line of wires to another, or decline responsibility altogether. But if they were bound by law to undertake and fulfil adequately-paid engagements, they would soon find means of settling terms of mutual arrangement by which the office where neglect or delay occurred should be mulcted duly.

"The public has a helpless sense of imbecile incapacity in the presence of those perky little magicians who manipulate and decipher the lightning with such autocratic unconcern. It might have a good moral effect if one of these worthies received a little penal castigation now and then. The pointsmen who neglect their switches on railways are liable to the law. And as lives may be lost by muddling a telegram for a surgeon as well as by turning a train on to the wrong line, an example now and then might be wholesome *pour encourager les autres*.'"

THE INTERNATIONAL EXHIBITION, 1862.

(Continued from page 246.)

J. Gressler & Co., Berlin, H. M. (Prussia, 1,402), exhibit a regulator in which the electrodes are carried on two little cars, which run down inclined planes to meet one another. The electrodes are held parallel to these inclined planes, and move equally. The motion of the cars drags a long armature past the poles of an electro-magnet, and when the current is of the required strength, or greater than that strength, the armature adheres to the electro-magnet, and stops the cars. M. Gressler also exhibits an arrangement in which one electrode only moves, and is arrested by similar means when a given current passes round an electro-magnet. These arrangements are cheap, but have several obvious defects.

Murray & Heath, H. M. (United Kingdom, 2,937), exhibit a lamp in which the upper electrode is fixed, or rather adjustable by hand only; the lower electrode is self-adjusting. The current, in passing from one pole of the battery to the lower electrode, is divided into two branches, one of which contains the usual electro-magnet, working the detent which regulates the rise of the lower electrode, and the other contains a rheostat or variable resistance, by the adjustment of which the proportion of the current passing through the other branch round the electro-magnet can be altered. Thus, a large portion of a weak current, or a small portion of a strong current, can at will be used to work the electro-magnet. The distance between the armature and the electro-magnet can also be varied, and still further increases the range of adjustment. The position of the light alters as the carbons consume, and the light is not automatically relighted if accidentally extinguished. It is not, therefore, in its present form adapted for lighthouses or similar purposes, but no doubt will give excellent results in the lecture-room, or in experimental investigations.

F. H. Holmes, M. (United Kingdom, 1,886), uses with his magneto-electric machine a lamp of his own invention, which produces a very regular and constant light entirely free from flashes. This lamp is somewhat similar to Duboscq's in principle, but differs from it in many important practical details. The construction is very simple; two cords are wound in opposite directions round two portions of one shaft of unequal diameters. The cord from the larger portion of the axis is led down under a pulley on the frame, which carries the upper electrode, and then up to a lever, the functions of which will be described presently. The bight of the cord under the pulley supports the upper electrode with its frame. Similarly the cord from the smaller part of the axis is led down under a pulley on the frame carrying the lower electrode, and then up to a pin which can be turned round by hand so as slightly to lengthen or shorten the cord. The bight of the second cord supports the lower frame and electrode. The upper frame would, if unchecked, fall down, unrolling its cord from the larger portion of the shaft, but winding up the other cord on the smaller part of the shaft, and consequently raising the lower frame and electrode. The rise of one and the fall of the other take place in the proportion of the diameters of the two parts of the axis. This movement is checked by a detent, gearing into a star escapement-wheel. The armature of an electro-magnet, A, frees this wheel when the current falls below a given strength, depending on the adjustment of an antagonistic spring attached to the armature; a continuous feed is thus produced exactly similar to that obtained from Duboscq's lamp. The pin already mentioned, by shortening or lengthening the cord of the lower electrode, allows its height to be adjusted with ease and accuracy, so as to bring the light into the exact centre of a reflector or lens if necessary.

The lever to which the one end of the cord of the upper electrode is secured is so centred that, by slightly rocking, it lifts or lowers the one end of the cord, and consequently the whole frame or electrode; this motion is confined within small limits by stops. A weight on the other end of the rocking lever nearly balances the weight of the upper frame, and an armature attached to this weight hangs immediately over a second electro-magnet, B. When no current circulates through the lamp, the weight of the frame and electrode overbalances the counterpoise. The armature of B is lifted from the magnet, and the end of the lever, carrying the cord, falls, lowering the upper electrode, but when the current is passing, the armature of B is attracted, and with the aid of the counterpoise, pulls down one end of the rocking lever, lifting the cord, and consequently the upper electrode. The first-named electro-magnet, A, then works the detent, regulating the continuous feed. If the current fail for an instant—if, for instance, the light be blown out—the armature of the second magnet flies up, the upper electrode falls into contact with the lower, re-establishes the current, and again is at once drawn up to the original distance, so that the lamp is relighted.

If the interruption lasted more than a very short time this part of the action would fail, for the escapement-wheel is also freed by the cessation of the current, and the continuous feed would jam the two points together, or break the sticks of carbon. Thus, although this lamp relights itself if momentarily extinguished, it will not do so if extinguished for more than a very short time, and it cannot be lighted at a distance by simply turning on the current, or extinguished by interrupting the current. In order to extinguish the lamp it is necessary to lock both the rocking lever and the escapement-wheel; and to light it, it is necessary to free both of these parts.

Mr. Holmes' lamp, together with his magneto-electric machine, have, since the 2nd of June last, worked successfully at Dungeness lighthouse, exclusively in the hands and under the care of the Trinity House. By the kindness of the Brethren, the writer is

able to state that it has since that time been accidentally extinguished only four times, and then only for a moment, having been immediately attended to; the light was observed to quiver occasionally, and also to wax and wane; the circumstances which occasioned these changes being the varying presence of iron in the carbons, slight variations in the position of the carbons relatively to each other, and the presence during some months of an abundance of large moths in the lantern. These, it will be observed, are very slight defects, and Mr. Holmes has, moreover, informed the writer that the four momentary extinctions took place when the light was under the charge of a man who had had no previous instruction, and who had been sent temporarily to take the place of one of the regular attendants absent on leave. Mr. Holmes also doubts whether the other slight defects can be in any way attributed to his lamp; but whether this be so or not, it is evident that an electric lamp which, with no greater failures than these, can be left for months in the hands of the lighthouse attendants, without any supervision on the part of the inventor, must possess great excellence. Mr. Holmes uses a slightly different lamp for signals, or other purposes for which the light requires to be frequently extinguished and relighted.

V. Serrin, Paris, M. (France, 1,437), exhibits an electric lamp with a regulator possessing very remarkable qualities. This lamp is lighted by simply turning on the current, and again extinguished by interrupting the current; it can, therefore, be lighted and extinguished at a distance as often as may be desired. This could not be done by any other lamp exhibited except, perhaps, by that of Mr. Hart. The construction of the instrument is as follows:—The wheels regulating the approach of the two electrodes are driven by the predominant weight of the descending electrode with its frame, and the relative motion of the two electrodes is determined by gearing, in the ratio of their consumption, so as to keep the light in one position. The motion is stopped by a toothed wheel and detent, and this detent is released by the armature of an electro-magnet. So far the lamp does not differ essentially from those of Duboscq and others. The frame or tube carrying the lower electrode is capable of moving vertically to the extent of three or four millimetres, by being fixed on an articulated parallelogram, which oscillates on two centres.

This vertical movement is quite independent of the rise of the electrode produced by the gearing, which pushes the carbon up through the oscillating tube by means of a metallic chain; the greater or less tension of the chain, and the friction of the rod in the tube, in no way impede the freedom of oscillation of the parallelogram, owing to the peculiar arrangement of the chain, which is led horizontally from the fixed gearing to a pulley in the oscillating system. It passes round one quarter of this pulley, and is carried down the rod in which the lower electrode is fixed. The tension of the chain as arranged pulls up the rod and electrode through its gearing tube, and pulls the oscillating system horizontally against its bearings, but does not interfere with the freedom of motion. An armature of soft iron is fixed to the bottom of the parallelogram; this armature is a flat horizontal bar bent down at right angles at each end. The two vertical projections embrace the two poles of a straight electro-magnet at a distance of about two millimetres. The motion of this armature is in a plane perpendicular to the axis of the electro-magnet, the attraction of which tends to bring the centre of the two end flanges in a line with its own axis. The object of this disposition is to obtain considerable range without the very rapid variation of attraction which occurs when an armature moves to or from a magnet in the direction of its axis. An adjustable spiral spring lifts this armature and the oscillating system; the tension of this spring is adjusted so as nearly to balance the weight of the whole oscillating system. The detent, which stops or releases the wheelwork, is also attached to the parallelogram, but the escapement-wheel forms part of the fixed gearing. The rise of the parallelogram brings the carbon points a very little closer, and at the same time allows one or more teeth of the escapement-wheel to pass, so that the wheelwork revolves, and the carbon points are both moved forward a little; the descent of the parallelogram stops the wheelwork, and separates a very little the carbon points. The rise and fall required to free and stop the escapement-wheel are quite insignificant, but the escapement-wheel is so made that the parallelogram and detent can descend much further than is necessary simply to lock the wheel.

The instrument works as follows:—When no current is passing through the lamp the upper electrode descends until it comes in contact with the lower electrode, and presses down the oscillating parallelogram until the detent on the parallelogram stops the wheelwork, when no further motion can take place. As soon as the current flows through the electrodes which are thus in contact, the electro-magnet powerfully attracts the armature, and carries down the lower carbon to the required striking distance by depressing the whole oscillating system. The light immediately appears, and as the two points are consumed by the action of the current, the armature slowly rises, owing to the decrease of the current consequent on increased resistance. At a certain point the detent frees one tooth of the escapement-wheel; the wheelwork then revolves, and brings the two carbons a little closer, in much the same manner as in Duboscq's lamp, without, however, affecting the position of the oscillating parallelogram in the least degree. The current is thus again re-established at the required strength, and tooth after tooth is released, as the carbon points wear, by the almost imperceptible rise and fall of the oscillating system. If by any accident the current becomes too strong, the parallelogram removes the lower electrode a little further off, and by thus increasing the resistance, still maintains a constant current. If the current becomes suddenly much weaker (if, for instance, the light is blown out), the attraction of the armature ceases altogether, and the parallelogram springs up until the carbon points touch; at that instant the current is re-established, the armature again descends, and the light is in the same condition as before. The strength of current at which the detent is released simply depends on the adjustment of the spring which tends to lift the oscillating system; if this spring be weak, the detent will be released only when a very weak current is passing, and consequently the points will burn very far apart; if the tension of the spring be increased, the oscillating system will rise, even when a strong current is passing, and the carbon points will be kept comparatively close. The action of the lamp appears perfectly regular and to be depended on, and the details are extremely well considered. It has, however, one or two defects—the extreme sensibility of the oscillating system is in itself an evil, for the carbons never acquire a fresh position of equilibrium until after one or two oscillations; this defect is aggravated by the weight of the moving parts, which is necessarily large. The nature of the magnetic attraction, varying rapidly according to the relative position of the armature and the magnet, would be fatal to the invention were it not for the peculiar arrangement of the armature already described; but even this arrangement does not entirely remove the evil.

Two of M. Serrin's instruments were used in connection with M. Berlioz's electro-magnetic light, and either could at any moment be lighted or extinguished by simply turning a commutator—a most important advantage in many applications. For instance, this lamp could be used at the top of a mast, or under water, where other forms would be entirely impracticable. The light was tolerably constant, but was subject to occasional flashes which were very evident in the neighbourhood of the light, but which the inventor states are not visible at a distance.

W. D. Hart, Edinburgh (United Kingdom, 2,906), exhibits a lamp of entirely different and very ingenious construction. The lower electrode is fixed; the upper electrode is held in a brass rod roughened on its surface, and capable of a slight motion up or down. Round one part of this rod there is a hollow circular wedge of conical shape divided longitudinally into halves which are hinged to a common base, and tend to fall outwards. A ring surrounds this wedge, and is attracted to the armature of an electro-magnet to which it is attached, and which lifts the ring when a current passes. When the battery is not in action the roughened rod is in its lowest position, and simply rests by the upper carbon on the lower carbon; when the current is turned on, the armature of the electro-magnet lifts the ring, and compresses the halves of the hollow wedge which now grasp the rod; the upward movement of the armature and ring continues, and lifts the roughened rod and the upper electrode to the required distance from the lower electrode. This distance can be adjusted by screws. The lamp continues to burn until the current so far fails that the armature can no longer carry the upper electrode, the armature and attracted ring then fall down, the wedge loses its hold on the roughened rod, which by its own weight falls still further, until the two carbon points touch, when a powerful current is re-established, and the upper electrode again lifted to the original distance from the lower one.

This lamp may therefore be said to work by a succession of throbs; and it is difficult to believe that the light can be even approximately continuous. It can be readily adjusted to any size

of battery which can show the light, by altering the lift of the upper rod. It is also very simple and cheap. A committee of the Royal Scottish Society of Arts reported in 1858 that Mr. Hart's lamp gave as continuous a light as the electric lamps then before the public. It could be lighted at a distance by simply turning on the current.

(To be continued.)

LAND TELEGRAPH TO HONG-KONG AND THE CHINESE PORTS.

A COMMITTEE of the House of Commons, taken aback by some answers made to them by Brinsley, the hydraulic engineer, in regard to a project under consideration, asked him abruptly what he thought Providence intended rivers for? "What do I think Providence intended rivers for?" repeated Brinsley, "why, to feed navigable canals, of course!" If Brinsley was entitled to the joke for the sake of the good philosophy in it—though the Chinese, whose commerce depends so much on their canals, would probably think that his *raison d'être* for rivers was quite sufficient—much more might our utilitarian merchants be pardoned if they thought that God had created electricity with a special eye to the electric telegraph. In this mode of application it has subserved our highest worldly interests to an extent which could never have been anticipated. It has quickened all the pulses of the commercial world. It has gone far to annihilate the disadvantages, without impairing the benefits, of distance. It has brought London nearer to Glasgow, for purposes of communication, than Eaglesham or Busby, without causing our city to be obscured in the shadow of its mighty presence. It has brought the rich and fruitful countries that are washed by the blue waters of the Mediterranean Sea, within quicker reach than Campbeltown or Islay, without drawing them away from under their fructifying skies. In short, it has brought every place to which its magic wires are stretched far nearer for purposes of supply, while leaving them all their former advantages for purposes of production.

There is no nation on the earth to which the telegraph has become so important, and to which it offers such splendid advantages, as our own. It is one of our grandest boasts that the sun never sets on our possessions. Before he leaves us in the evening he is already smiling on our friends in Canada. Before he has lost sight of British America his beams are lighting up the distant shores of New Zealand and Australia; he turns his eye from Australia only to let it light on our vast empire in India; and before he bids good night to the Himalayas, he is kindling the golden ball of St. Paul's Cathedral, and the gilded vanes of our Glasgow churches, and calling our teeming millions to their daily work. To connect these scattered portions of our vast empire—to knit them together as by a beautiful and delicate nervous system, so that all the parts, with the advantages of separation, shall enjoy the advantages of proximity, and the remotest extremities shall feel and thrill with every pulsation of life from the central heart—this is a work which one agency alone can effect, and that agency is *the telegraph*. The splendid advantages to be derived in every way—political, military, and commercial—from bringing our colonies and dependencies into constant, easy, and rapid communication with one another, are too obvious to need specification; and our Government, we are glad to see, is becoming more and more alive to its importance.

Last month we called attention to the approaching completion of the telegraph wires from England to India, *viâ* Arabia and the Persian Gulf, and to the good prospect there now is of seeing the telegraphic system of Europe and India speedily united by this route. We shall thus be in full telegraphic communication with Calcutta, and—*viâ* Calcutta—with Rangoon and Shooe-Gyen (Shway-Gyeen) in Eastern Pegu, over the following distances, in geographical miles:—

London to Belgrade, in European Turkey	900
Belgrade to Constantinople	450
Constantinople to Bussorah, in Asiatic Turkey	1100
Bussorah to Kurrachee, in British India	1050
Kurrachee to Calcutta	1155
Calcutta to Dacca	135
Dacca to Rangoon	480
Rangoon to Shooe-Gyen	130

This gives a total air-line length of 5,400 miles of telegraph from England eastward; or, by the addition of one-fourth to cover deviations in following existing roads along the route, about 6,750 geographical miles in all. Of these, there will be 5,625 miles (that is, the entire line, save from England to Belgrade) either on British territory, or under British control, and worked by English signallers. We are thus on the eve of realising what may well take its place as one of the greatest wonders, and certainly one of the most valuable achievements of this age—an unbroken line of telegraphic communication from England to Shooe-Gyen, on the south-west of China.

There are few of our merchants, if they look at their maps and follow the route we have described, who will not feel their mouths watering, in a figurative sense, when they find the telegraph so *terminating* in Pegu. Their eyes will traverse, with eager and wistful glance, the narrow overland space that separates Shooe-Gyen from that mighty gateway of our commerce with China—Hong-Kong; and they will naturally ask themselves WHY the Home and Indian Governments, having wisely and successfully carried the wires so far, should not carry them the little farther that is thus needed to bring Hong-Kong into direct telegraphic communication with London? The distance, compared with that which will so soon be traversed by the telegraph to India, is insignificant, and 120 miles of it would be over British territory. We should then, according to the detail statement of the Messrs. Sprye hereon, have 279 miles from the north-east frontier of British Pegu, across Burmah, by the cities of Kiang-Tung and Kiang-Hung, to Sz-mau (Esmok) on the south-west frontier of China. Thence along the imperial roads, down the Pearl and West River valleys, through six or seven of the principal Southern Chinese cities, to Canton, would be 757 miles; with 70 more from that city to Hong-Kong. These distances yield a total of only 1,226 geographical miles, or, by adding one-fourth, as before, for deviations, 1,534.

Being then on the eve of completing an unbroken line of telegraphic communication from London as far as Eastern Pegu, a distance of 6,750 geographical, or about 7,100 English miles, it becomes a question of great and pressing importance, especially to our merchants and shipowners, in view of the vast interests which we now have springing up in China, whether the Home and Indian Governments should not take the steps necessary for carrying the wires over the 1,500 miles of land that separate us from Hong-Kong. The project is not new. For several years the Messrs. Sprye, whose names are well known in connection with our commercial system in the East, have been pressing on both Governments the importance of thus extending the Indian wires, *by land*, from Pegu to Hong-Kong and the open ports of China; and have spared no pains in endeavouring to satisfy them and the public as to the practicability of the proposal. In anticipation of the completion of our telegraphic connection with India and Eastern Pegu, their project (which embraces the opening up of trade with the whole of the rich inland provinces of Western China) is daily attracting a larger share of public attention; and the Manchester Chamber of Commerce have now, for a second time, memorialised the Government in its favour. Having stated its nature and extent as fully as our space allows, we may proceed, when leisure permits, to discuss its manifest merits, for England and India, over the Russian-Siberian-Mongolian line to the north of China.—*Glasgow Herald.*

THE CONSERVATION OF FORCE.

IF a boy snaps one marble against another of the same weight with such precision of aim that the two come in contact exactly in line of their centres, the marble that is snapped will stop in place of the other, while the one that is hit will move forward with the same velocity as the first and in the same direction. The marble first set in motion loses its force, but this force is not destroyed, it is transferred to the other marble, and is thus preserved—or conserved. As action and reaction are equal, it is held as a self-evident truth, that matter once in motion can be stopped only by setting some other matter in motion, and this principle is called the conservation of force.

This doctrine is now generally associated with that of the mechanical theory of heat. It is supposed that the universe is filled with an extremely subtle fluid, imperceptible except through its vibrations to any of our senses. The theory further imagines that the minute particles of this fluid have vibrating motions of various kinds. If we fasten one end of a clothes-line to a post, and

take hold of the other end and shake it up and down, we shall see undulations or waves run along the line. The several particles of which the cord is composed do not move in the direction in which the waves move, but while each wave starts at one end of the rope and runs to the other, any given inch of the rope simply vibrates up and down. If we shake the end of the cord horizontally, we shall produce vibrations in a different direction; and if we whirl the end around in a circle, we shall produce those of a still different character, the waves will be apparently spiral, though each particle of the rope will be revolving in a small orbit. There are other kinds of waves conceivable in the particles of fluid which cannot be represented by a rope.

Now, the theory is, that one kind of vibration in the ethereal fluid produces the effects and the phenomena which we call heat; another kind light; another electricity; another magnetism; and another chemical affinity. It is supposed that when heat is converted into electricity, the peculiar vibrations which affect our senses as heat are stopped, and that in stopping they start those vibrations which we recognize as electricity.

It is also supposed that when a body is heated, the heat vibrations of the ethereal fluid are imparted to the several atoms or molecules of the heated body. And, as all the substances with which we are acquainted are more or less warmed, it would follow that all of their particles are in continual motion. In the same way, when a body is electrified, its particles are presumed to receive the electric vibrations.

The fact that light, heat, electricity, magnetism, chemical affinity, and mechanical force are all mutually convertible one into another, is one of the strong arguments in favour of the truth of this theory.

This theory is the most comprehensive that has ever been conceived by the mind of man. It proclaims that all of the varied and complex phenomena of the universe, from the revolutions of the nebulæ to the growth of a lily, result from the single fact, that matter has got in motion and cannot stop. It recognizes but one force in the universe, *vis viva*, or the force of moving bodies. It also suggests the possibility of explaining all phenomena, leaving one circumstance only beyond the pale of human knowledge—what it was that first set matter in motion.

THE ORIGINATOR OF SUBMARINE TELEGRAPHY.

WE quote the following communication from the *Scientific American*, of the 14th inst.:—

Will you allow me a little space in your excellent journal to correct an error of fact, respecting the origin of submarine telegraphy, to which my attention has been specially directed in a marked number of the *Telegraphic Journal*, of London, sent me thence by an unknown friend.

In a notice in that journal of April 2nd, of the late Mr. Brett's collection of pictures, there is this incidental remark, "The late Mr. J. W. Brett, who was designated by Professor Morse, *the father of submarine telegraphy*, &c."

I have never designated Mr. Brett, nor any one else, "father of submarine telegraphy," having always claimed to have first proposed, and personally laid and operated the first submarine telegraph myself.

Mr. Brett I knew well; he was a personal and highly-esteemed friend, and I knew that he supposed himself to be the first who had proposed a submarine line in 1845. In conversations with him I always insisted that not only the first proposal, but the first actual execution and operation of such a line belonged to me. I told him I had unanswerable evidence of the fact. This announcement to him I saw gave him uneasiness, and after I left Paris in 1858, for Porto Rico, he wrote me a letter under date of November 15, 1858, in which he asked me to give him the history of my connection with submarine telegraphy. To this letter I replied from Arroyo, Porto Rico, December 27, 1858, quite at length, giving him minutely its history. In that letter (a press copy of which I have by me), I showed him that at least as early as 1838, I had made the proposition of an Atlantic telegraph to Robert Walsh, Esq., the American Consul in Paris; for Mr. Walsh testifies to that fact of his own move, without my knowledge at the time, in one of the American journals, of which he was the foreign correspondent. But I referred him also to my letter of September 27, 1837, to the Secretary of the Treasury, published in the Congressional documents, in which letter I suggest the submarine method of constructing a telegraph line. I referred him also to my letter to another Secretary, in August, 1843, in which I make the distinct prediction of a future Atlantic telegraph, as a deduction from experiments I had made. For in the autumn of 1842, I had carried into effect the proposition of a submarine line in the harbour of New York, laying out the line personally from Castle Garden to Governor's Island. This was an acknowledged success by the journals of the day, and for this success I received the gold medal of the American Institute. This medal fixes a date (1842) unmistakeably. Mr. Brett rests his claim on the fact that, in 1845, he addressed a letter to the British Government, proposing oceanic and subterranean telegraphs. The year 1845 is the earliest date to which he appeals, and at that date he had only suggested a plan of submarine telegraphs to the British Government, while three years before I had actually constructed and operated, in New York harbour, a submarine telegraph line.

It is obvious, therefore, that I could not have designated Mr. Brett as the "father of submarine telegraphy." The *Telegraphic Journal* marks these words professedly, as a quotation from a written or printed document of mine. I have never written or printed any such admission. The nearest to such an admission is the following extract from the historical letter alluded to, which I wrote to Mr. Brett. After giving him a detailed account of the steps I had taken in submarine telegraphy, I say, "I have read your account of the origin and progress of the ocean telegraph with deep interest, and if chronology, by its rigid dates, gives the origin of submarine telegraphy to me, it cannot detract from you the undoubted merit of having independently originated the project of submarine intercommunication, and successfully carried it out, too, in Europe, to a useful result. I esteem and honour you as the *Father of European Submarine Telegraphy*, and I rejoice that both the honour and the profits have been so justly awarded to you."

In thus awarding to Mr. Brett, in that letter, the honour of being an independent originator of "European Submarine Telegraphy," I ought to say that if there are other claimants to that position in Europe, I do not pretend to decide between them. I based my remark to Mr. Brett solely on his representations to me, believing him to be, as he was, an honourable and high-minded, as he certainly was, a generous and worthy man. If the supposed admission on my part that Mr. Brett was the "father of submarine telegraphy," is founded on this letter of mine to him, it is seen at once that it is a misquotation in the *Telegraphic Journal*, and (as I am willing to believe) through mistake, the important qualifying word "European" was left out, which is necessary to be inserted to make the quotation conform both to my letter and to the truth of history.

New York, April 26, 1864. SAMUEL F. B. MORSE.

THE PERSIAN GULF TELEGRAPH.

OUR last detailed notice of the Persian Gulf telegraph expedition extended to the landing of the end of a section of the cable on the isthmus (Muklub) which separates the Gulf of Oman from that of Persia, and we mentioned that, while waiting for the Tweed and Assaye to arrive with further sections, Colonel Stewart, Colonel Goldsmid, and Sir Charles Bright proposed to pay a hasty preliminary visit to Bushire, Bussorah, and Fao, for the purpose of inspecting the arrangements made at those places for landing the cable ends, and establishing permanent stations. However, after the vessel which brought us that intelligence left, Colonel Stewart thought it advisable to accompany Colonel Disbrowe, the British agent at Muscat, to that place. Accordingly, the Coromandel went to Muscat with all her party except Colonel Goldsmid, who remained at Mussendum; and we understand that an interview which Colonels Disbrowe and Stewart had with his Highness Syed Soweynee, the Sultan, resulted in arrangements likely to be very advantageous for the protection of the telegraph cable where it passes through his territory.

Colonel Stewart having completed his business at Muscat, and the Coromandel having taken in sufficient coal for the rest of her work in the Gulf, she returned to Mussendum: not, however, to Malcolm's—which, as we before explained, is the inlet on the eastern or Oman side of the promontory —but to Elphinstone's inlet, which is on the western or Persian Gulf side of Ras Mussendum. On a small island in this inlet, and not on the mainland as at first intended, the telegraph station has been fixed. This rocky island of bare limestone is just large enough for the purpose to which it has been put. At present all the officials who are to remain there are in tents; but Colonel Stewart has designed a most commodious building, for which the island itself and the neighbouring rocks will afford an unlimited supply of excellent stone.

The Arabs of the villages about the inlets—who, before Colonel Stewart's visit to the Imaum of Muscat, were rather inclined to be troublesome—are now very well behaved, so that there seems to be little or no reason to fear that, even in wantonness, they will do any injury to the cable where it crosses the narrow isthmus between Malcolm's and Elphinstone's inlets; and a visit which the Imaum proposes to pay to the spot very shortly is likely still farther to foster the goodwill which they seem now inclined to exhibit towards our people. Besides, there can be no doubt that people so utterly devoid of property as these will not lightly do anything which might put an end to the solid advantages which are constantly accruing to them in the shape of presents and liberal pay for very light work. In addition to the accommodation on the island, there are two hulks comfortably fitted up as dwellings for the telegraph employés. One is moored off each end of the island. These hulks are the old Indian navy vessels Euphrates and Constance, both of which have done good service in their day. We can well believe that the Indian naval officers who accompanied the expedition could not restrain a sigh at seeing the vessels, in which they have often braved the dangers of the deep with friends and companions now scattered far and wide, converted into mere hulks, however useful the purpose to which they are to be applied. When the question of what name should be given to the

island and station was mooted, it was purposed to call them after Colonel Stewart, but the colonel himself decided that it should be called after the inlet, Elphinstone Island. The view around it is not beautiful, but grand and imposing; encircling it is the calm, clear water, blue from its great depth, and almost always so still as to reflect, with photographic accuracy, the clear, sharp outlines of the stern, towering, bare rocks, which seem almost to enclose an inland lake.

Fish of various kinds are almost the only kinds of food afforded by the place itself; rock oysters are very plentiful, and almost every day some of the party set out with hammers, and bottles of the proper piquant accompaniments, in order to vary the monotony of their ordinary repasts by a dozen or two of "real natives." The amusement, however, is not open to every one, as on many stomachs these oysters seem to produce much the same effect as Dr. Cockle's antibilious pills—at least they get the credit of doing so. A few fowls and eggs are the only other kind of food to be got at Mussendum, and the stock of these in the neighbouring villages is already nearly exhausted.

But arrangements have been made to secure a constant supply of all kinds of food, &c., from the island of Kishm (Bassadore Island). The intention which originally existed of ultimately fixing the station at the town of Kussab, which lies at the entrance of the inlet, has, we believe, been quite abandoned, as there is every reason to believe that any advantages which that place may at present possess over Elphinstone Island are easily obtainable for the latter; while its disadvantages—in a sanitary point of view, and from want of shelter for the hulks in bad weather, as well as the distance at which it is situated from the point where the cable crosses the isthmus, and where it is, of course, most liable to injury—are irremediable.

We fear we cannot describe the Elphinstone Island Telegraph-station as a favourable resort for those who have it in their power to select a place of residence; but we do not see why, when permanent buildings have been erected, water-condensers and ice-machines set to work, and a regular supply of fresh food is kept up, it should compare at all unfavourably with Aden; and our readers are probably aware that statistics prove Aden to be the second healthiest station of the Bombay army. Elphinstone Island, too, will possess at least one advantage over Aden, for though it will not have a weekly mail from England, yet it will be in hourly communication with the whole of Europe, and those stationed there will know the great events of the day before the Viceroy himself.

Colonel Stewart has not neglected any available means of rendering the expatriation of the telegraph employés as little irksome as possible; he has provided each station with a good library, carpenters' tools, rifles for rifle-practice, boats, &c. Till arrangements can be made for a Royal navy vessel to be stationed at Mussendum, the guardianship of our people is committed to the Bombay marine gunboat Clyde, commanded by Lieutenant Hewitt, of the Indian navy; she will probably be shortly relieved by the Hugh Rose. Each of the hulks also has a brass 24-pounder under the charge of an European gunner.

All the arrangements we have been describing were made between the completion of the first section of cable (from Guader to Elphinstone Island) and the arrival of the Tweed and Assaye with the next sections—those from Elphinstone Island to Bushire and on to Fao. On the 12th of March the Zenobia arrived with the Tweed in tow, and a day or two afterwards the Semiramis brought in the Assaye. At the same time the Victoria came in from Kurrachee towing the flat Hyderabad, which is to be used as a hulk at Fao. The Dalhousie next made her appearance with the two hulks already referred to. When these vessels arrived, they found the Coromandel and the gunboat already there, so that for a few days Elphinstone Inlet saw a sight which it never saw before, and is not likely soon to see again—six steamers (three paddles and three screws), four sailing-vessels, and a flat riding at anchor together.

The ships having arrived, no time was to be lost in continuing the laying of the cable, so the Zenobia was sent off without dropping her anchor to coal at Bassadore, and in the meantime the shore end of the Tweed section of cable was landed on Elphinstone Island, and attached to the same instrument as that to which the extremity of the section from Guader had already been laid. The Zenobia came in on the 18th, and the same afternoon she took the Tweed in tow, and proceeded out of the inlet and on her course for Bushire, the cable paying over the Tweed's stern with the utmost regularity and ease. The weather continued as favourable as could be desired during the whole time, and in less than eighty hours 360 miles were laid down without a single hitch of any sort, and what was most gratifying, it was found that, as the cable became subject to the pressure of the sea, so its conducting powers improved. The section on board the Tweed was, as had been anticipated, exhausted about fifty miles to the east of Bushire, off a part of the Persian coast called "the asses' ears;" the Assaye was then brought close to the Tweed, and the beginning of her cable spliced on to the end of that just laid down; this done, the Zenobia took the Assaye in tow, and proceeded with her into Bushire Roads, where the end of the cable was landed by the telegraph steamer Amberwitch. Thus the telegraphic chain from India to Europe was completed as far as Bushire. On the following day (25th of March) the Amberwitch landed the end of the next link towards the west—viz., that from Bushire to Fao—the station at the mouth of the Euphrates where the submarine communication is to give place to the overland. Indeed, the land-line from Fao to Bussorah is already completed. When this piece, about 140 miles in length, to Fao was laid, as it was to be the day after the Semiramis started for Bombay, the only link wanting in the long chain from India to England would be part of the distance from Bussorah to Bagdad, which, as we before stated, would have been completed ere this but for the opposition offered by the wild Arabs of the district.

We were very sorry to learn that Lieutenant-Colonel Stewart had been unwell for two or three weeks while lying in Elphinstone Inlet, after returning from Muscat, though we are happy to be able to state that when the Semiramis left he was quite recovered, and able to attend to business as usual.

The particulars given above regarding the progress of this great work left the submarine cable at Bushire on the 25th of March. On the following day the laying down of the remaining portion from Bushire to Fao, at the mouth of the Euphrates, was proceeded with; and on the evening of Easter Sunday, March 27, the ship anchored in the Khor-ab-Dallah, a shallow delta very near the spot at which the terminal station of the submarine line has been established. Thus far the great bulk of the work was successfully completed, but there still remained one operation, which was, perhaps, the most difficult of the whole. The end of the cable had to be carried from the Khor-ab-Dallah across a spit of mud some miles wide at Fao. The difficulty which first presented itself was to get the cable across the six or eight miles of shallow water which intervened between the cable-ship (Assaye) and the edge of the mud-bank. This could only be done in a flat-bottomed boat, and accordingly the Comet, a flat-bottomed steamer belonging to the Bombay marine, and commanded by Lieutenant Bewsher, which does the Government work between Bussorah and Bagdad, was put into requisition, her two 9-pounders and all her coals having been taken out in order to make room for the cable. At first it was proposed to land the cable on the Khor-ab-Dallah side of the mud-spit, and carry it across to Fao, but ultimately another course was adopted. Enough cable to stretch across the mud-spit to the Khor-ab-Dallah was placed in the Comet; one end of the piece she delivered on board the Hyderabad, a flat-bottomed hulk moored off Fao, which for the present, at any rate, is to be the telegraph-station; the other end was taken on shore, and laid along a trench through the mud which had been prepared for it. Off the Khor-ab-Dallah end of the trench the telegraph steamer Amberwitch, Lieutenant Stiffe, was waiting with another section of cable; the end of this was spliced on to that in the trench, and the Amberwitch steamed away towards the buoyed end of the main part of the cable, paying out as she went along. When we reached the Assaye, the buoyed end was picked up and spliced on to the section of cable that had just been paid out, and the telegraphic communication between India and the Euphrates was complete. This took place on the 8th of April.

But between the anchoring of the telegraph squadron in the Khor-ab-Dallah on Easter Sunday and the completion of the work to Fao an accident happened to the cable, which, though at first the cause of a good deal of annoyance on account of the suspension of communication with India which resulted from it, ended in giving increased confidence in the work, by showing with what ease such accidents as must necessarily be anticipated can be repaired. During the above night, March 27, and up to eleven o'clock the following day, the communication along the line was perfect; and reports of the progress made were sent to the Governor-General and Sir Bartle Frere; a good deal of business connected with the expedition was also transacted through the cable, but the wire became suddenly dumb, and the electricians at once saw that a solution of continuity had taken place somewhere. The question was, where and of what nature was the break? Of course there could be no doubt as to which section was the faulty one; it could only be the last—that from Bushire—because the piece of cable extending between any two stations is complete in itself, and quite distinct from any other; though the further end of one section and the near end of another are always attached by the same instrument, and can be readily brought into direct communication. But though the possible locality of the break was thus limited to one section, yet that section is nearly 150 miles long, and the fault might exist in any one of the 264,000 yards of cable of which those 150 miles consist; and all these 264,000 sites of the fracture had an average depth of 25 fathoms—that is, 150 feet of water over them. Yet—will our readers believe it?—within half-an-hour of the cessation of communication through the wire, the exact locality of the fault was determined to within a third of a mile, and even the extent of injury to the cable was ascertained. It was found that the wire only was affected, its gutta-percha covering, and the outside casing of iron wire, &c., remaining intact. The distance from the anchorage to the break was calculated at 90½ miles. When we hear that all these particulars of the accident were confidently stated within half-an-hour of its occurrence—that all the preparations for repairing the break were based upon them with as much confidence as if they had been mathematical certainties—and that they were found to be absolutely correct, must afford the highest gratification. This is a noble result of the "philosophy of fruit," as Lord Bacon loved to call the system of investigation to which he was the first to call men's minds.

The Amberwitch (which is fitted up with every convenience for paying out or repairing the cables), with Messrs. Webb and Woods, the principal members of the engineering department of Sir Charles Bright's staff, proceeded towards the spot at which the tests from the Khor-ab-Dallah side showed the fault to lie, and there she met the Zenobia returning with the

electricians from Bushire, the tests from that side having, as we before mentioned, given the same results as those from the Khor-ab-Dallah. Mr. A. P. Young, late Indian navy, who, with Commander Bradshaw, R.N., of her Majesty's ship Severn, has been engaged in preparing charts of the exact positions of the cable, was on board the Zenobia, and according to the directions furnished by him from the chart of the cable, Lieutenant Carpendale, the commander of the Zenobia, laid down a buoy almost exactly abreast of the fracture. In the immediate neighbourhood of this buoy, the Amberwitch began to drag with a grapnel across the course of the cable, and in about seven or eight hours the cable was hooked, and a "bight," or loop of it, dragged up to the bows of the vessel. It was immediately cut through, and one end, with a buoy attached dropped into the sea, while the other was coiled down in the vessel as she steamed towards the exact point at which the tests continued to show the defect to lie. When the steamer came over the exact spot, and the broken part of the cable began to be raised off the ground, the electric current began to flow through it again as if it were perfect. This was the result of the bending of the cable as it left the ground, which caused the broken ends of the wire to come again into actual contact. As soon as the part in which the fracture was had been got on board, the cable was again cut, the end of a new one spliced on to it, and the Amberwitch steamed back, paying out the new piece as she went along, till she reached the end which had been buoyed; to it the end of the new piece was spliced. The whole operation of dragging for the cable, cutting it, inserting about two miles of new, and making two splices, each splice occupying about six hours, was completed in less than forty hours, and would have been done more rapidly had not two joints, when partially completed, required to be made over again. Very great credit is due to the gentlemen of Sir Charles Bright's staff who effected the repair, and to the marine surveyors whose accuracy in delineating the exact course in which the cable was laid, rendered it possible to determine at what exact point any given length of cable would have been passed over. These particulars being furnished to Lieutenant Stiffe, his intimate knowledge of the Persian Gulf enabled him to steam straight to the point indicated. When it is considered how many different classes of facts have to be accurately ascertained before any particular part of the cable can be hit upon, the rapid approach towards perfection in submarine cable-laying which the laying of the Persian Gulf cable shows, will be more thoroughly appreciated.

The Amberwitch having returned to the Khor-ab-Dallah, and the weather, which had become exceedingly boisterous, though fortunately not till after the repair of the cable had been completed, having moderated sufficiently to allow of the end of the cable being picked up, the extreme end was again brought into communication with the galvanic battery, and messages passed to and fro through the whole length of the line—that is, through 900 miles of cable, between the Khor-ab-Dallah and Guador.

Reference was made at the beginning of this article to the completion of the cable-laying from the Khor-ab-Dallah, up to the telegraph hulk Hydrabad at Fao, but we believe it is almost impossible to convey by word an idea of the tremendous difficulties over which British "pluck" and determination have triumphed in this part of the work. One mile had to be laid through mud so soft that the men engaged in laying it, and the engineers who were superintending them, could not stand upright at all, but had to drag the cable after them as they propelled themselves in a sitting position; and when they did reach firm ground—the mud-spot above referred to which separates the Khor-ab-Dallah from Fao—the cable had to be cut into mile-and-half lengths and carried by hand: in this work several hundred Arabs were employed. Across the mud-spit the cable is buried in a trench about thirty inches deep. This was dug under the superintendence of Lieut.-Colonel Goldsmid and Commander Bradshaw, who, regardless of discomfort, took up their quarters in a tent in the middle of the mud. Colonel Goldsmid, with Mr. Johnson, the Vice-Consul at Bussorah, made the necessary arrangements for securing Arab labour, and Commander Bradshaw laid down the course of the trench.

The manner in which all the members of the expedition work together for the attainment of their common end is most commendable; and no small share of the happy result must be attributed to the Director-General, Colonel Stewart, and to Sir Charles Bright, whose kindliness and urbanity generally prevented any of the clashing and jarring which but too often occur where a great number of persons of different professions are associated in an undertaking of moment and responsibility, and where a somewhat ambiguous authority is delegated.

We have now, in our successive accounts of Colonel Stewart's expedition, traced the course of telegraphic communication between India and Europe, to the point where it ceases to be under direct British control. A message from any part of India passes the Indian frontier at Kurrachee, is sent along the land line (250 miles) to Guader on the Mekran coast of Beloochistan. At Guader it is transferred to the submarine cable, by which it is conveyed to Fao at the mouth of the Euphrates, having passed through and been repeated at Elphinstone Island (Mussendum) and Bushire. At Fao it is transferred to the Turks, who send it along their land line to Bussorah, and on towards Bagdad as far as the line is completed. At present about 170 miles of the distance is incomplete; the unfinished portion lies between two completed parts, the work having been pushed on simultaneously from each town. Over the unfinished part the message is conveyed along the river by steamer or by *kossids*—that is mounted horsemen—who travel as nearly as possible in a state of nudity, so as to offer no temptation to the cupidity of the lawless inhabitants of the country through which they pass. Coming again upon the telegraph, it is sent still by the Turks through Bagdad and Mosoul (Nineveh). A telegraph station amid the ruins of Nineveh! Then across the Persian frontier to Diarbeker, and on by Sivas and Angora to Scutar, where it crosses to Constantinople.

We need not trace its course farther. Even in the present incomplete state of the line between Bagdad and Bussorah, a message from England which reaches Bagdad at the time when one of the river steamers is starting for Bussorah, may be delivered in India in about $4\frac{1}{2}$ days; but one going the reverse way, and which must be conveyed by a *kossid*, or against the stream in a steamer, will take two days longer.

We are happy to say that Colonel Stewart anticipates a speedy solution of the difficulties which impede the completion of the line in Mesopotamia; they arise solely from the hatred borne by the Arab inhabitants to their Turkish masters. Their feelings to the English are very friendly, and if the Turkish Government would permit us to construct the line it might be easily completed; but they are exceedingly jealous of us, and insist on doing it themselves, while the Arabs seize every opportunity of annoying and obstructing them. As may be imagined, the Turkish authority over such lawless people is merely nominal, and does not really extend beyond the nomination of their sheik or governor. But recently they have been endeavouring to gain a firmer hold, and with that view endeavoured to purchase the title to the soil. To this the sheik consented, and went to Bagdad to conclude the arrangement; but the Arabs refused to allow their birthright to be bartered away, or to submit any longer to the authority of the man who had attempted to barter it; accordingly they broke out into open rebellion against the Turks and their sheiks; hence the interruption to the telegraph. Now, however, the Turks have consented to appoint a new sheik, and one who is favourable to the work; he will be invested at Bagdad immediately. Colonel Kemball, the British Resident at Bagdad, has been chiefly instrumental in bringing about these amicable arrangements; but he did not succeed in doing so without very great difficulty, nor until the Pasha at Bagdad had received orders from the Porte to be guided by his advice.

Our last news from the Euphrates left just as Colonel Stewart was starting for Bagdad, to consult with Colonel Kemball regarding these and other matters. He was to be accompanied by Sir Charles Bright, Colonel Goldsmid, and his personal staff. The Bombay marine steamer Coromandel was to convey them as far as Bussorah; the rest of the passage was to be made in the flat-bottomed steamer Satellite, which had just arrived in the river; she is made over to the telegraph department.

The Bombay Marine has played a most important part in the laying of the cable. The superintendent, Captain Young, C.B., late Indian navy, directed the whole of the marine arrangements, having the cable-ships fitted for the work on arriving from England, providing towing-power for the paying-out ships, and vessels for the despatch of the large quantities of stores required at the different stations. We understand that Captain Young's arrangements have been most complete and satisfactory, which indeed is proved to be the case by the fact, that no delay or accident has occurred to any of the large number of vessels employed. There have been no less than nine steamers engaged in the work—six of them large sea-going vessels, the other two flat-bottomed river boats, and in addition to these which have been actually employed in the paying-out operations, at least seven large ships have come round the Cape with stores and the cable. The Coromandel has been the head-quarters' ship throughout the expedition, being commanded by the senior Bombay Marine officer, Lieutenant G. O'B. Carew, late I.N., through whom Colonel Stewart conveyed all his instructions to the commanders of the other vessels. Colonel Stewart and Sir Charles Bright, when cable-laying was not actually going on, lived on board her. She was sometimes employed in piloting and sometimes in towing. The Zenobia, paddle steamer, commanded by Lieutenant T. C. R. Carpendale, late I.N., was employed in towing the cable-ships while actually paying out. She has greater power than any of the other paddle-steamers which were employed in the expedition, and Lieutenant Carpendale and his officers quickly got accustomed to the kind of duty required of them, and by their close attention to the directions constantly sent from the cable-ship, greatly facilitated the ease and success with which Sir Charles Bright and his staff were enabled to carry out the delicate operation of paying out the cable. We anticipate Colonel Stewart's official report on the operations with great interest.

The only work now remaining to be done, is the laying of a piece of cable along the Mekran coast from Guader to Kurrachee, as a supplement to the land line which already exists there. As we before mentioned, the land-line has been working most satisfactorily for about a year; but in so important a matter as the telegraph between India and England, it is thought best to use every possible means of securing an uninterrupted communication.—*Times of India.*

NEAPOLITAN TELEGRAPHS.—The telegraph in Naples was inaugurated, under the auspices of the State, on the 31st July, 1852, and has since been extended in a very satisfactory manner, although at some expense to the Government. The telegraph offices now open in the kingdom of the Two Sicilies number 248, producing 1,370,000f., while the expenditure has amounted to 1,736,000f. We appear to be able to manage these things better, and at less cost in England, by private enterprise.

ON THE PATENT LAWS.

DISCUSSION.

(*Continued from page* 250.)

Mr. WALTER HANCOCK said that the policy and operation of the patent law had been forced upon his attention by an experience of its working for nearly twenty years. No one could deny that that working was unsatisfactory, sometimes grossly unjust; so much so, that it was even possible (as was suggested by Mr. Hawes) for a man to have his invention snatched away from him, and if he neglected to follow it up closely to the doors of the Patent-office to see, by operation of law, the legal title to his property conferred upon another. But this monstrous scandal, although within the letter of the law, was diametrically opposed to its spirit; it was an evil not necessarily inherent in the law, but possible only from its present lax and clumsy administration. To an enterprising manufacturing country like ours, the subject was one of great importance and of great difficulty. The views entertained as to the policy of any law for the protection of patent right were as wide asunder as the poles, for inventors too often insisted that it was the duty of the State to establish a system for their especial and ample protection, overlooking the fact that the law owes duties to the public as well as to the inventor; on the other hand, persons entitled to great weight maintained that the policy of patent right was essentially vicious, and opposed to the principles of a sound economy, inasmuch as it created a monopoly. Between these two extremes there was ample room for a sound and beneficial law. The staunchest opponents of patent right would not deny that the inventor of a new and useful invention was entitled to a substantial reward of some kind. We were told, indeed, by a few that invention, like virtue, would prove its own reward; this would only apply to the pure philosopher, who pursued the study of science for its own sake. We were told that the State should reward inventors, but what was to be the nature of this State reward? A decoration, a riband, or a nomination to a legion of honour? He did not wish to undervalue these acknowledgments, but they were not the considerations that would weigh with the body of our countrymen as a stimulus to invention. Then we were told that the State ought to give pecuniary rewards. He maintained that it would be impossible to work out such a problem either satisfactorily or economically. How difficult it was now to get the Admiralty or any Government body to appreciate or take up any new invention, however valuable. If a department of the State were charged with the duties of examining and dispensing rewards for new inventions, was it not probable that instead of 3,000 we might have 30,000 claimants per annum? And should we not require for this purpose a machinery and a body of experts more extensive and costly than that which was advocated for the preliminary examination of patents? Another serious objection would be that these rewards would be a heavy charge upon the State, whereas the present law was not only self-supporting, but left a surplus, which, as Mr. Webster justly said, ought to be applied wholly to the encouragement of invention. He could not but come to the conclusion that for the people of this country, who appreciated everything by its value in pounds, shillings, and pence, the only feasible reward was the commercial one, such as was conferred by patent right: because such a reward would usually be as nearly as possible equivalent in value to the benefit which the public themselves (by the purchase of any patented article or process) considered that the inventor had conferred upon them by his invention. Now it was easy to "give a dog a bad name," to raise an unfair prejudice against patent right by stigmatising it as a "monopoly," as a remnant of the laws of olden times. He considered that Mr. Webster had demolished the argument that patents were monopolies, by showing that they deprived the public of no existing right or benefit, because they referred only to new trades or processes created. He (Mr. Hancock) must demur to the proposition of the chairman of the council, that "patent right was a remnant of the law of olden times." Placed side by side with invention, patent law was of comparatively recent date. In olden times there was no patent law; there was no necessity for it; nor was there any necessity for copyright. Inventions were "few and far-between," and it was while in the actual enjoyment of that reward for which the author or inventor of the present day had to strive so hard, that many of the great works and inventions of old were completed. To what higher reward could Virgil aspire, when engaged upon his Æneid, than the patronage and bounty of Augustus? Or Horace than that of Macenas? Was it not at the court of Hiero, of Syracuse, that Archimedes made the great discovery of specific gravity? But, if the proposition were correct, that patent right was a remnant of the laws of olden times, that alone would be no argument for its abolition. If we wished to descend from the proud position that we occupy of being the greatest, freest, richest nation in the world, we could not do better than begin by abolishing some of our laws of the olden time, such as trial by jury, which was said to have existed about 1,000 years, Magna Charta for about 650, and Habeas Corpus, which might be said to date from the same century as our patent right. He contended that what was vicious in the olden laws of monopolies was abolished by the Act of 1624, and that the legislature exercised a wise discretion when they excluded from its operation the patents for inventions. So far, therefore, from regarding patent right as a law that ought to be abolished, he looked upon it as a necessity of the present time. This subject had been fully discussed at the meeting of the British Association at Manchester in 1861. Mr. Curtis (then Mayor of Manchester) gave a striking instance of the necessity of a patent law. His firm had spent upwards of £10,000 in the perfecting and introducing a new machine; without a patent right it would have been open for any engineer to have availed himself of all this outlay, and actually to have made and sold the improved machine, and got a profit, at a price at which the inventor himself, with this outlay to make up, could not possibly compete. If the opponents of patent right charged its advocates as monopolists, surely their own principles too nearly approximated to those of the communists. He (Mr. Hancock) could give a more striking instance, drawn from his own experience, of a new invention and manufacture that would not have been prosecuted but for the patent law. About twenty years ago there was introduced into this country and to this Society a substance new to us—gutta-percha—and for the introduction the Society rewarded Dr. Montgomerie with its gold medal. It was introduced as a scientific curiosity, in the hope that means might be devised for rendering it a useful material in the manufactures of this country. Hitherto it had answered no such purpose, although it had existed for probably 5,800 years. It could not be obtained without great difficulty; it was necessary to penetrate tropical forests, inhabited by tigers, at a distance of 15,000 miles from home. It was not, therefore, without considerable labour and enterprise—it was not, in fact, until after the undivided attention of three gentlemen for a period of three years, and the assistance of others, and at a total expenditure of nearly £25,000, that any manufacture for profit could be attempted. He would confidently ask, would the inventors and capitalists have combined to do this but for the protection of the patent laws? What had been the result? The public had been largely benefited by the many purposes to which this substance had been applied, but especially by its application to submarine telegraphy. When we recalled that the old Atlantic cable by one message saved this country upwards of £50,000, that during the Crimean war the Black Sea cable was estimated to have saved this country upwards of £1,000,000 and that besides this we had for twelve years enjoyed submarine telegraphic communication with the continent, it must be obvious that the benefits, direct or indirect, conferred upon the public by gutta-percha were incalculable. He would grant that the gutta-percha patents had produced an immensely handsome reward. He would grant that, as was too often notoriously the case, the bulk of that reward had been reaped, not by the inventors, who conferred the benefit, but by the enterprising company who worked the inventions, and to whom for their enterprise some degree of credit was unquestionably due; but he would firmly maintain that the benefits conferred upon the public had been immeasurably greater that those conferred upon the inventors and their co-adjutors, and that, in the true spirit and interest of the Patent Law, the contract entered into by the crown on behalf of the public, by which, in return for the invention, the crown granted a patent right for the limited period of fourteen years, was a just and beneficial conract.

Mr. J. A. MACFIE said he felt very much honoured and gratified in having the opportunity of being present and listening to the discussion, and he was only sorry that the cause which he espoused had so few advocates in a place where, above all, he should have thought that it would have found friends to support it. He was glad that the Hon. Secretary of the Association for Promoting Social Science had addressed the meeting so well and so ably, and he was afraid that in having to follow him he should prove the great advantage of professional men over plain men of business. The subject was a very large one, and had been most ably brought before their notice by Mr. Webster, whose paper embraced questions which had been very often debated—namely, right of property in inventions, what reward ought to be given to men of genius and men of skill who benefited the public by their inventions, the present state of patent law in Britain, and the best remedies for the evils which were universally admitted to exist. These subjects could not be considered without also taking into consideration the state of affairs with regard to inventions in other countries with which England stood in relation, and the changes which had come over British commerce and British manufactures by the introduction of free trade. The principle which had been advocated by many in this Society, when reduced to different language, was, that every man who made an invention had a right to prevent others from doing what he had done. That was, in plain terms, the proposition which they were asked to receive. Without going very far into the subject, he would only remark that it was very fortunate for us that we did not live in the days of Adam and his immediate descendants, for then everything was new and everything was an invention, and our race would still have been savages. He could not think that anything which would not apply to such a state of society could be consistent with the Divine law, and since he took such high ground as that, they would allow him to say that he thought that many of the things which were said on this subject were hardly consistent with the principles of the religion which prevailed in this country. Those who doubted the advisability of this system of rewarding inventors by means of monopolies were not averse to any amount of honours. One of the speakers had rather disparaged honours, but he could say for himself that he would rather have some honour, some acknowledgment from the Queen, some proof that he had served his country, than he would receive a thousand pounds; and he was quite sure that there were many who were influenced by the same feelings. But although they heaped honours on those who really deserved them, yet he was sorry to say that one of the defects of the present system

was, that it was no honour to be a patentee, for they were only a class of persons many of whom pretended to be inventors without having done anything at all meritorious or deserving of the privileges which they enjoyed. With regard to the question of property in inventions, he would offer one or two observations to show that, in the ordinarily accepted sense, this could not exist. What was bought was not the invention, but the secret. The patent was the recompense, not for the invention, but for the secret, and the proof of that was that a reward was given to any man who imported an invention, and in that case the reward was not for an invention, but for having communicated to the country a secret; therefore the property was not in the invention, but in the secret. Canada, acting on this principle, had stipulated that she would give no patent but to those who were resident within her own territories. He only gave this as a proof that, even in our own colonies, where they had got emancipated from the old traditions of our country, they actually acted upon the principle that there was no inherent or natural property in inventions. It occurred to him, however, that our friends on the other side of the Atlantic would show a little more good sense if they would consider the public interest rather more even than that of those favoured few who made inventions. In point of fact, in their way, they did consider the public, because their practice simply amounted to this, that they presented gratuitously to the colonies of Great Britain the produce of all the inventions which we pay for, and thereby hung a thought which required great attention in these times, namely, that the people of Great Britain were throwing upon the manufacturers of Great Britain the great burden of patents, and at the same time, as Mr. Hawes had very properly stated, they were calling upon them to compete, under free trade, with all countries in the markets of the world, and with those who were using our inventions without paying for them, while our manufacturers were obliged to pay the heavy royalties which patentees demanded. What had to be considered was, the best means of getting rid of these heavy burdens, which would prevent Britain from running successfully in the race of commerce. Another proof that there was no natural property in invention was afforded by our own law, because if there really was any property in an invention, it would go to a man's heirs and successors, and would not go from him at the end of the fourteen years; this, however, was not the case, and it plainly showed that this was not what we called "property." Again, another excellent suggestion had been made by Mr. Webster, and was entitled to all the weight which anything coming from him deserved, and that was that there ought to be the privilege of a compulsory sale, which could not, of course, exist in the case of property. The second proposition of our patent laws, when reduced into shape, was that every man who found out a new way of doing a thing, must first undertake a very heavy task. Before a man could use his own invention he must do what would be the work of a lifetime, namely, inquire whether anybody else had the plan patented. If he made any discovery, he must first of all, before he could do anything with it, go to the patent office, and to all the various manufacturers who used the particular machine in connection with which he had made his discovery, and ask them if they had ever seen his way of doing it before. Surely this was a most preposterous state of things! He said it deliberately, that if he was a patentee he must either neglect his business to attend to his patent, or else he must neglect his patent. What he held was, that if a man was a patentee he must go to all parties connected with his trade, and tell them what his plans were, and make arrangements with them. Another hardship was for a man to find himself duped after he had made his arrangements with a patentee; but he was sorry to say that the present laws enabled persons to be victimised in that way. Above all, it must never be forgotten that times were changed, and that we were changed too, and that we were not consistent in maintaining patent laws, which only tended to restrain trade.

Admiral Sir EDWARD BELCHER said the question of absolute invention, of the strain on the brain in bringing the first idea into satisfactory action, could only be comprehended by those men who had toiled, and dreamed, and expended time and money, in perfecting an invention. Inventions which deserved the protection of patents should only be discussed by actual inventors. If it were assumed that the great men who had risen to eminence in their different pursuits, saw no bright light ahead which was destined to reward them for their labours, it was most probable that, counting the cost, the waste of time, and the ungenerous return which inventors experience from the public, they would at once exclaim, "Better far stick to my work with the tools I have than fool away my time that others may benefit by my exertions." Inventions, however, in many instances, were not the result of absolute study for a decided purpose; in some cases the result of mere accident. An instance of this had occurred to him without the slightest idea of seeking for or taking advantage of it. He was engaged in turning a very hard wood, which threw off very fine bright sulphur-coloured shavings and dust, and had invited a party to dine on board his ship. His steward warned him he had barely time to dress, and brought him hot water. It was near the equator, and the exertion of turning had produced profuse perspiration. He washed his face with the plain water and got rid of the fine dust. The moment he begun to use the soap to his hands and nails they were immediately dyed of a bright red, and in that state he was compelled to receive his guests. That, however, was his secret: he had, *malgré lui*, discovered a dye. Now what was the effect of a discovery made under such circumstances? For the moment he followed it up, amused himself by dyeing flannel, cloth, &c., but his time was too valuable; he had other duties demanding his attention; it would not pay, and it passed unnoticed. So would it be with engineers and workmen—unless they saw the course open, by the protection afforded by patent, they would in a similar manner neglect discoveries of the utmost importance.

Mr. GEORGE CLARKE said, that when in a discussion of this kind men of such distinction as Mr. Hawes, the Chairman of the Council, Sir William Armstrong, and others who had evinced the highest talent and the soundest discrimination, expressed the views which they had, it became the duty of inventors and of the public, whose interests were really identical, to stand up in favour of protection to inventors. There had even been some hints in the legislature as to an intention to abolish the patent laws, and he thought it was, therefore, incumbent upon inventors to do their best to refute the hollow arguments by which it had been attempted to be shown that inventions should not have protection. Mr. Hawes said that protection by patents was detrimental to our own manufacturers, because it held out a premium to manufacturers abroad to reproduce our best productions. He confessed that he had read that observation with surprise, and he could not even now quite understand it. It was supposed that from a specification foreigners could at once seize all the ideas of an original inventor, and be able to carry his plans out. Unless that was the view taken, where was the danger to the interest of the country in publishing specifications? They all knew, however, the extreme difficulty of carrying out inventions. It was not always the original inventor who carried out the invention, but it was by the combination of his talents and the capital of others, which he was able to command by having secured a monopoly, that at last the public was presented with all the fruits of the invention. Surely the original inventor had the best chance of bringing his invention to bear, and he certainly thought that the danger to this country was very little of its trade being injured by foreigners taking up our new inventions. But now that free trade existed, supposing the result to ensue which was stated in the arguments of those who stood up for the public, then it would be to the benefit of the public if the foreign manufacturer should be more successful than the original inventor in carrying the invention into practice. They all knew how difficult it was to seize the ideas of others from any written description. It was almost impossible to understand an invention without diagrams and drawings. He knew a case in his own experience in which, in order to introduce spinning machinery into Belgium, although the drawings and specifications were published, the foreigners were obliged to send a skilful workman over to England to engage himself in the manufactory. He saw no reason, therefore, on that ground why patents should not be granted for inventions. Another point which had been referred to was the great number of patents which had been taken out, and the great loss, as it had been said, to the public. This fact, which had been put forward so prominently as an argument against the patent laws, and a condemnation of inventors, was, in his opinion, the highest proof of the great utility of protection, even in the shape in which the law now afforded it. He would not now enter into the present state of the law, which he admitted to be very defective, but what he was advocating was the existence of protection to inventors. It was nothing but the patent law which had brought forth this great number of patents. It was the hope of reward which had stimulated inventors, and which had induced men to become inventors when otherwise they would not have been so. That which happened in all other cases happened in this case; for after all, the shape which a patent took was that of a commercial enterprise, and nothing more. They must evoke the spirit of competition, and if they did that then they would at once obtain those results which had raised this country to the pinnacle of greatness. The great merit of the existing patent law was that it stimulated inventors to compete for the great prizes which were only the rewards of success. They all knew, when they started in the race, that they could not all be successful, but this was the case in all professions and occupations. Therefore, this argument, which was used against protection to inventors, was really the strongest argument in its favour, for it was quite a mistake to suppose that the number of applications for patents represented the same number of real inventions. The number of patents worked in this country, in proportion to the population, was less than in Prussia. He had just been told that the number of patents granted there was only seventy per annum; but the system there was very exclusive, and the committee of experts refused any patent which they did not understand, and, therefore, the number was very much reduced.

(To be continued.)

LAW INTELLIGENCE.

NEWALL v. ELLIOT AND OTHERS.—This was an action brought by the plaintiff to recover damages for the infringement of a patent obtained for improvements in apparatus employed in laying down submarine electric telegraph wires. The improvements consisted—first, in coiling the wire or cable round a cone; secondly, the supports placed cylindrically outside the coil round the cone; and lastly, the use of rings in combination with the cone. At the trial, which took place at the sittings after Hilary Term, the jury found a verdict for the plaintiff. Mr. Montagu Chambers obtained a rule last term, calling upon the plaintiff to show cause why the verdict should not be set aside and entered for the defendants, on the ground that the verdict was against the evidence, and a misdirection on the part of the learned judge.—Mr. Grove, Q.C., the Hon. George Denman, Q.C., Mr. Quain, and Mr. Markly showed cause.—Mr. Montagu Chambers, Q.C., Mr. Cleasby, Q.C., and Mr. Bidder supported the rule, but had not concluded their arguments, which have occupied several days.

TELEGRAPHIC NEWS.

THE TELEGRAPH BETWEEN MARSALA AND TUNIS.—It is reported that the Italian Government intend to lay a telegraph cable between Marsala and Tunis, which will place Malta in direct communication with Algeria.

THE LIABILITY OF TELEGRAPH COMPANIES.—The Court of Common Pleas in St. Louis, U.S., has recently decided that telegraph companies are responsible for any loss or damage occasioned by the incorrect transmission of messages.

PRUSSIAN TELEGRAPHS.—At the central telegraph station of Berlin no fewer than 126 wires are employed. The number of messages sent daily vary from 6,000 to 7,000. The telegrams which pass through Berlin are not included in the above numbers.

COMMUNICATION WITH AMERICA.—It appears that a convention has been signed between the French, Portuguese, Italian, Brazilian, and Haytian Governments, for the establishment of telegraphic communication between the continent of Europe and America. A total subvention of £480,000 will be given jointly by these governments, who guarantee the neutrality of the line.

PORTABLE TELEGRAPH.—A new telegraph has been adopted by the Americans for army operations. The current is magneto-electric, generated by turning a small crank. Neither battery nor acids are required, the apparatus is compact and convenient, and may be carried in a soldier's haversack. We hope to be able to publish a description of this ingenious contrivance shortly.

EUROPE AND AMERICA.—In the recent message of the President of the United States to Congress we find the following important allusion to the opening up of telegraphic communication between America and Europe:—"Satisfactory arrangements have been made with the Emperor of Russia whereby an uninterrupted line of telegraph will be laid between that empire and the Pacific coast. I recommend to your consideration the establishment of an international telegraph to traverse the depths of the Atlantic Ocean, and also the necessity which has arisen for telegraphic communication between the capital and national forts on the coast and borders of the Gulf of Mexico.

BALATA.—At a recent meeting of the Polytechnic Association of the American Institute, the president read his usual summary of the scientific and industrial news of the season, from which we select the following item:—The valata tree, growing in Guinea, yields a juice which is used by the natives instead of milk in coffee. M. Serres states that this juice is capable of being worked into a product much more flexible than gutta-percha, and in every way superior to it.—Dr. Parmelee: Mr. Chairman, I have had eight samples of valata submitted to me for examination. I have as yet investigated its physical properties only. It is not softened by immersion in hot water, it can be vulcanised, and seems to be intermediate between gutta-percha and india-rubber. I understand that it can be procured in large quantities.

AMUSEMENTS OF TELEGRAPH CLERKS IN INDIA.—A correspondent of the *Times of India* communicates the following from a private letter received by him, dated Jubbulpore, 11th April last:—"It appears that a telegraph employé at the Rewah station fired at and wounded a Brahminee bull in that city. The townspeople became infuriated, and, armed with matchlocks, swords, and stones, they rushed to the telegraph bungalow, which they eventually surrounded, threatening the telegraphers with their lives; and in this jeopardy they kept them for several hours, ere the mob could be reasoned into reconciliation. The affair did not go far enough to partake of a political character, but the cause was sufficient to have ended in more mischief than it did; and if some substantial check on such frolics in a native state be not effected, we may some day learn that the whole of the local staff of the telegraph department has been butchered at some isolated Mofussil post, through the indiscretion of some lad. Since the receipt of the above letter I have been informed that on the occurrence of the disturbance the head signaller at Rewah utilised the wire instantaneously, by informing the chief commissioner of the circumstance, whom it threw sufficiently off his equilibrium to cause the commanding officers of all the large military stations within his jurisdiction to be put on the *qui vive.*"

DESTRUCTIVE FIRE AT SILVERTOWN.—On Thursday morning a very serious conflagration occurred on the premises of the Silver's India-rubber and Telegraph Cable Company, situate on the banks of the Thames, and nearly opposite the Royal Dockyard at Woolwich. The buildings cover several acres of land. The adjoining village of Silvertown is wholly inhabited by people employed at the factory. The fire broke out in a timber built manufactory, 250 feet long and 30 to 40 feet deep. It contained machinery for dressing solution, and dressing departments, with drying and spreading shops, armoury, and boiler-house, all of which were severely damaged. In the armoury, which was destroyed, were deposited the rifles of the Silvertown Rifle Corps. The company has issued the following notice:—"We have the satisfaction to inform you that the fire which occurred at our works on Thursday morning will very slightly, if at all, interfere with the execution of orders for our general manufactures." The premises were fully insured.

THE following important letter appeared in the *Times* of the 23rd inst.:—The Persian Gulf Telegraph.—Sir,—The paragraph under this head which appeared in the *Times* of the 19th inst. having given rise to the impression that an interruption had taken place in the working of the line since its completion, I beg to state that the paragraph, which was taken from an Indian paper, had reference to a temporary accident which occurred to the cable while it was being submerged, in the month of March last, and which was immediately rectified. Subsequent advices received from Lieut.-Colonel Patrick Stewart, C.B., have assured us of the continued well-working of the line through the whole length. The messages of the Government are now transmitted twice a-week, each way, between Constantinople and India, by means of steamers on the Tigris.—I am, sir, your obedient servant, LATIMER CLARK.—London, May 21.

SWISS TELEGRAPHS.—During the past few days the following paragraph has been going the round of French newspapers, and is considered by our neighbours across the water as a reflection upon the administration of M. Fould, their Finance Minister:—This year, for the first time since Switzerland was constituted into a political confederation, the Helvetic Budget showed a deficit. This unheard-of fact caused a considerable sensation in the twenty-two cantons. The Federal Council became disquieted, and extreme measures were taken to get rid of what the fellow-countrymen of William Tell considered a scandal. The means resorted to were very simple, merely consisting of an increase in tolls on bridges and on telegraphs, but the honour of the country is considered safe, as the year will pass without a deficit.

MISCELLANEA.

TELEGRAPH LITERATURE.—The literature of the telegraph has recently been increased by the publication of some ingenious tables and pamphlets, by the Count de Lauture. As the titles of these publications will possess a certain value to those persons interested in the transmission of secret intelligence, we subjoin them: "Grammaire du Télégraphie; Histoire et Lois du Langage; Hypothèse d'une Langue Analytique et Méthodique; Grammaire Analytique Universelle des Lignaux." "Short Explanation of the Sketch of the Analytic Universal Nautical Code of Signals." "Analytic Universal Telegraphy; an International Telegraphic Language, simple, accurate, and three times shorter than the system at present in use, presenting in its practice neither the difficulties nor inconveniences of other ciphers." "Sketch of Tables for the Analytic Universal Telegraphy, composed on the supposition of Morse's instruments and signals being used." "On the Telegraphic Transcription of Chinese Characters; a Table with Four Elementary Signals." It is asserted that, with these tables of one square foot, the 40,000 or 50,000 characters and words of the Chinese are transmitted by telegraph with the utmost accuracy, and with one-third of the signals which the same message would require in any other language, or by any other method. The Count's system of telegraphic communication for the army is said to be exceedingly ingenious.

PERSPICUOUS MESSAGES.—The value of speedy telegraphic communication is often alluded to, and justly appreciated in this go-ahead age, but the rapidity, though marvellous, is as nothing when compared with the wonderful *correctness* with which messages are forwarded. As an instance of this, we have much pleasure in quoting the following telegram *verbatim*, as it was received by a gentleman from his friends in Liverpool:—"Macinosh ovfsshelmed vitto eval vants, badly to be relieved con yeu find room for amat Malta il vernels non at Gibraltar can de inducen to go thert. Telegraph immediately."—*Malta Observer.*

ON THE PURIFICATION OF SULPHURIC ACID.—The best means of obtaining sulphuric acid entirely free from arsenic fully bear out the fact recorded by MM. Bussy and Buiguet—viz., that arsenic, in order to pass during distillation, must be present in the state of arsenious acid. I have, however, been led to employ a different mode of purification, chiefly with a view to ensuring the complete absence of all nitrous products, and obtaining a pure acid from the very first, and of thereby obviating the necessity of changing the receiver—a most dangerous operation when distilling sulphuric acid. If the acid contains nitrous compounds, I heat it in a porcelain capsule to a temperature of about 110° C., with a small portion of oxalic acid, till the latter is decomposed, and all effervescence has ceased; about ¼ or ½ per cent. is amply sufficient for nearly all samples of commercial acid. It is best to add the oxalic acid before heating, and to stir constantly till

the reaction is completed. I now allow the acid to cool down to about 100°, and to add to it a solution of bichromate of potassa in sulphuric acid, or some of the salt itself in fine powder, until the pure green colour at first produced by the formation of sesqui-oxide of chromium is replaced by a yellowish green, indicating an admixture of chromic acid in the free state. The acid so prepared, being now distilled, passes from the first perfectly free from all impurity. The addition of the bichromate has another advantage—viz., that if it be first of all applied to a small sample of the commercial acid, it indicates the presence of free sulphurous acid, as well as of arsenious acid, and either of these being present, we may presume on the absence of nitrous compounds. No doubt permanganates would answer equally well; but the bichromate of potassa, which is cheap and easily procured, is so convenient and inexpensive as to leave nothing to be desired.—*F. Maxwell Lyte.*

ARTIFICIAL RAINBOW.—The *Cosmos* speaks highly of M. Duboscq's contrivance for imitating a rainbow, in a French theatre. He employs an electric light, made by 100 Bunsen elements. Its rays are transmitted in a parallel direction by means of a lens through a slot in the form of an arc, to a double convex lens of very short focus, from which the rays pass to a prism, and emerge with sufficient divergence to make an effective rainbow, during the ordinary illumination of the stage, on a screen 18 or 20 feet distant.

CURIOUS ELECTRICAL PHENOMENA.—Professor Tyndall publishes the following account of some curious electrical phenomena observed by Mr. R. Watson, and a party of tourists, in ascending a portion of the Jungfrau Mountain in Switzerland. Mr. Watson, in a letter to Professor Tyndall, says:—"On the 10th of July, 1863, I visited, with a party of three and two guides, the Col de la Jungfrau. The early morning was bright, and gave promise of a fine day, but as we approached the Col, clouds settled down upon it, and on reaching it, we encountered so severe a storm of wind, snow, and hail, that we were unable to stay more than a few minutes. As we descended, the snow continued to fall so densely that we lost our way, and for some time we were wandering up the Lotsch Sattel. We had hardly discovered our mistake when a loud peal of thunder was heard, and shortly after I observed that a strange singing sound, like that of a kettle, was issuing from my alpenstock. We halted, and finding that all the axes and stocks emitted the same sound, stuck them into the snow. The guide from the hotel now pulled off his cap, shouting that his head burned; and his head was seen to have a similar appearance to that which it would have presented had he been on an insulated stool, under a powerful electric machine. We all of us experienced the sensation of pricking or burning in some part of the body, more especially in the head and face, my hair also standing on end in an uncomfortable but very amusing manner. The snow gave out a hissing as though a heavy shower of hail were falling; the veil on the 'wide-awake' of one of the party stood upright in the air, and on waving our hands the singing sound issued largely from the fingers. Whenever a peal of thunder was heard the phenomena ceased, to be resumed before the echoes had died away. At these times we felt shocks, more or less violent, in those portions of the body which were most affected. By one of these my right arm was paralyzed so completely, that I could neither use nor raise it for several minutes, and I suffered much pain in it at the shoulder-joint for several hours. At half-past twelve the clouds began to pass away, and the phenomena finally ceased, having lasted twenty-five minutes. We saw no lightning, and were puzzled at first as to whether we should be afraid or amused."

ELECTRICITY OF THE BLOOD.—At a recent meeting of the Paris Academy, Dr. Scoutetten returned to the important question of the electricity of the blood, and gave a historical sketch of the observations which have been made in the endeavour to prove, by an experiment which leaves no room for doubt, the electricity of the blood, and so arrive at the measurement of its electro-motive force. A large vase of porcelain, with a wide opening, and capable of holding a litre and a-half, was half filled with venous blood; in the midst of this was placed a porous vessel containing 400 grammes of arterial blood; two other small porous vases, of a capacity of sixty cubic centimètres, contained a solution of sulphate of zinc; these two vases were placed at the same time in the two sorts of blood. The zinc electrodes were placed in the solutions, and did not touch the blood. As soon as the electrodes, which were previously attached to the galvanometer by brass wires, were inserted in the liquid, the current was established. The experiments were made on the 29th of October, in presence of chemists, physicians, and distinguished *savans*. The blood was taken from a very old horse, in good health, which was to be slaughtered in the course of the day. The arterial blood came from the right carotid at the same time that the venous blood was taken from the left jugular vein; the porous vessel containing the arterial blood was then placed in the venous blood, and the whole appartus surrounded by a temperature of 40° centigrade, in order to prevent coagulation. The small porous vessels, containing the solution of sulphate of zinc, were sunk up to two-thirds of their height in the two sorts of blood. The amalgamated zinc electrodes were inserted lightly and simultaneously; the current manifested itself by the influence of the needle; it indicated, as in the first experiments of M. Scoutetten, that the positive current travelled from the arterial to the venous blood across the galvanometer. After having reached the stop, the needle oscillated and became fixed at 66°, where it remained for an hour. The galvanometer employed was Nobili's, with a coil of 10,000 turns. To measure the electro-motive force of blood, M. Scoutetten has had recourse, in this second series of experiments, to the method of opposition proposed by M. Poggendorff, and so ably carried out by M. Jules Regnauld. On placing the coupling wire of the two small porous vases in opposition to a normal wire at a constant current, he saw at first that the current became reversed, and hence he concluded that the force produced by the reaction of the two sorts of blood is comprised between zero and 4·50. Proceeding thence to more exact results, he arrived at last at the discovery that the electro-motive force sought was 1·82, that of Daniell's battery being 58; 100 representing the electro-motive power of pure zinc.

PATENTS.

APPLICATIONS FOR LETTERS PATENT.

1242. J. Hamilton, jun., improvements in electric telegraph posts.

NOTICES TO PROCEED.

833. W. E. Newton, improvements in electric or telegraphic conductors.

PROVISIONAL PATENTS.

1071. G. Schaut, an improved mode of transmitting currents of electricity.

1126. W. T. Henley, improvements in telegraph wires and cables, and in apparatus used in their manufacture, parts of which improvements are applicable to other useful purposes.

PRICES CURRENT OF INSULATING MATERIAL.

TO CORRESPONDENTS.

A report of the entertainment given by the Electric and International Dramatic Club will appear in our next.

The *Telegraphic Journal* can be had of Messrs. SMITH & Co., Strand; Messrs. DAWSON & Co., Cannon-street, E.C.; Messrs. KENT & Co., Paternoster-row, London. Messrs. HEYWOOD & Co., Manchester; at the various railway stations; and of all news-agents, &c., &c.; or it can be supplied, if preferred, direct from the Office on the following terms:—

	s.	d.
Quarterly	4	4
Half-yearly	8	8
Yearly	17	4

TO ADVERTISERS.

The *Telegraphic Journal* is the most effective medium for inventors, patentees, contractors, manufacturers of insulating materials and electrical apparatus to submit their various specialities to the consideration of secretaries and managers of telegraph or railway companies, and other persons engaged in electrical and telegraphic pursuits.

Clerks, assistants, manipulators, and instrument makers, seeking employment, &c., will find the *Telegraphic Journal* a ready means of making known their requirements.

Advertisements must be delivered to ensure insertion before SEVEN O'CLOCK on Thursday evening in each week. The charges for Advertisements are—

	£.	s.	d.
Whole page	4	4	0
Half ditto	2	10	0
Quarter ditto	1	7	6
Four lines and under (single column)	0	3	0

Single Advertisements from the country must be accompanied with stamps in payment.

PROFESSOR MORSE AND SUBMARINE TELEGRAPHY.

It not unfrequently happens that when a given scientific problem is to be solved, a theory developed by the exercise of the inductive faculties to be demonstrated by observation, or a mechanical difficulty to be overcome, the hope of honour or—what is less valued but more useful—pecuniary reward, will stimulate the genius of our race to labour in the direction indicated, and success is attained by independent workers at or about the same time. History furnishes us with many instances corroborative of this view. It is a moot point as to whether Trevethick or Stephenson are most entitled to the credit of having inaugurated the railway system of the world; M. Le Verrier and Mr. Adams both claim the discovery of the planet Neptune; and until within the past few years it was difficult to decide anent Mr. W. F. Cooke and Professor Wheatstone, whose several claims to the invention of the electric telegraph were contemporary. When disputes of this nature arise, it is very hard to discriminate between the respective claimants; and in adjudicating upon a case, it is almost impossible to avoid giving cause for dissatisfaction to one of the parties to the issue, however impartial the award. In the matter to which we are about to refer we shall not seek to conciliate individuals, but rather to elucidate facts with regard to one of the most important inventions of modern times.

In a letter which appeared in our last, Professor Morse denies to the late Mr. J. W. Brett the title of "father of submarine telegraphy," and claims "to have *first proposed* and personally laid and operated the first submarine telegraph" himself. The question as to who originated the system of subaqueous telegraphs may now be considered to be in dispute, and we shall shortly lay before our readers evidence which may not tend to corroborate our reporter's incidental remark, to which our attention has been directed, but which unmistakeably deprives the American professor's claims of all weight and importance. The most remote allusion to submarine telegraphy to which Professor Morse refers us is contained in a letter of his to the Hon. Levi Woodbury, Secretary of the United States Treasury, dated New York, 27th September, 1837, "on the propriety of establishing a system of telegraphs for the United States." In this document, after entering into a variety of estimates as to the probable cost of construction of an aerial line of telegraph, &c., the writer says:—"This mode would be as cheap probably as any other, unless the laying of the circuit in water should be found to be most eligible. A series of experiments to ascertain the practicability of this mode I am about to commence with Professor Gale, of our University, a gentleman of great science, and to whose assistance in many of my late experiments I am greatly indebted." Thus it will be seen that at the date of this letter Professor Morse had but conceived or obtained the idea of submarine telegraphy, and proposed to himself some inquiries as to its feasibility.

We will proceed with our narrative, bearing in mind one or two little but important facts—viz., that the telegraph at this time was but in its infancy; that the press of England readily trumpeted forth every incident of interest connected with the then, as now, wonderful science, and reported from time to time every experiment made or to be made by either Mr. Cooke or Professor Wheatstone; that America is but three weeks' voyage from England; and that at this date Professor Morse had introduced the subject of telegraphy to the Government of the United States.

In the month of March, 1837, Mr. Cooke and Professor Wheatstone had made arrangements for an experiment to test the practicability of telegraphing through a cable submerged in the river Thames between Somerset House and Mr. Walker's shot tower, in the vicinity of Waterloo-bridge, and the following letter, showing the progress of the work at that period, will be perused with interest:—

"Greenwich Ropery, 10th June, 1837.

"Sir,—We have proceeded with the operation of covering the copper wire with hemp, but previous to forming it into rope, we should be glad to submit it to your inspection and approval; and if you can make it convenient to come down here, we should feel obliged by your suggesting such alterations as may appear to you advisable.

"We are, &c.,

"— Cooke, Esq. (Signed) Enderby Brothers."

This rope or cable was first tried on the London and Birmingham Railway, under the direction of Mr. Cooke; while it remained there a heavy shower of rain wetted it through, and destroyed the insulation of the wires, and made it evident that some better plan of insulating the wires would have to be devised before success in submarine telegraphy could be attained. The project in contemplation was accordingly abandoned; and it was this fortunate accident that saved the parties the mortification which would doubtless have followed the ridicule and failure of the much-talked-of Thames experiment. Later in the same year Professor Wheatstone proposed another scheme, in which he intended to employ some earthenware tubes, which he had made for protecting the conductors from the influence of water; but Mr. Cooke dissuaded him from attempting it, representing to him that even if the porous character of the tubes could be obviated, their extreme fragibility would occasion frequent *contretemps*. These facts in themselves would be a sufficient answer to Professor Morse, but we have a yet more striking refutation of his assumptions.

Before the subject of submarine telegraphy had attracted any degree of attention in England, Dr. Sommering, of Munich, and Baron Schilling, of St. Petersburg, had not only proposed, but had actually conducted a series of experiments in the Russian rivers, before credible witnesses, to which Dr. Hamel, in his "Historical Account of the Introduction of the Galvanic and Electro-Magnetic Telegraph into England," thus refers:—"On the 12th of June, 1811, Sommering made some experiments to telegraph through water, first across a canal on the river Isar, and afterwards along the river itself." Some doubt has been expressed as to whether this evidence is admissible in the consideration of the question at issue, as it is most probable that Sommering simply employed the water as a conductor without metallic agency, as Mr. Haworth and others have done in later days, but without any practical results. We will not contend whether this can be considered a feature of submarine telegraphy, but will pass on to a very conclusive revelation made by the same author:—"In 1812, Baron Schilling [who was on intimate terms with Dr. Sommering] conducted some operations with a *subaqueous* galvanic conducting cord across the river Neva, at St. Petersburg." Schilling afterwards, in 1837, ordered a submarine cable to be made to unite Cronstadt with the capital, through the Gulf of Finland, for telegraphic correspondence.

From the foregoing it will be seen that Sommering, Schil-

ling, Cooke, and Wheatstone each proposed submarine telegraphy some time before Professor Morse dates his claim; and that the latter thought or knew anything of this branch of telegraphy prior to the announcement in America of Cooke and Wheatstone's contemplated Thames experiment, is not borne out by one iota of evidence. Professor Morse has been eminently successful in having introduced the telegraph into the United States from this country, and has been handsomely rewarded for his 'cuteness. He espoused the art of telegraphy in its early days, promptly availed himself of every improvement made known in Europe, and with the assistance of an able chemist in Dr. Gale, and a skilful mechanician in Mr. A. Vial, he was enabled to perfect the transmitting instrument which now bears his name. Beyond this he has no title to consideration with Sommering, Schilling, Weber, Gauss, Steinheil, Cooke, and Wheatstone.

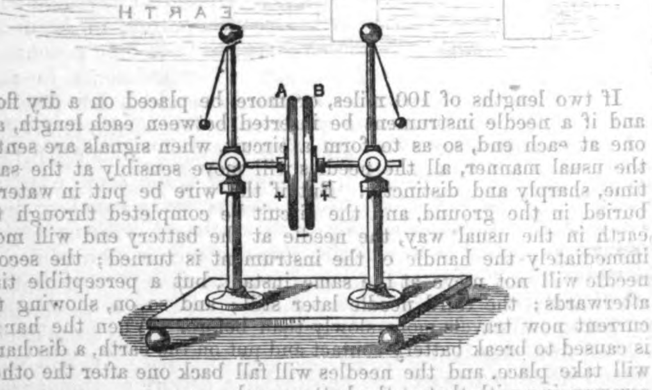
INDUCTION.

WE this week place before our readers an interesting extract from the instructive and valuable work of Mr. R. S. Culley, which was reviewed in the early numbers of this journal. The subject is one but little understood, even by our most advanced electricians. Mr. Culley has explained it in a clear and intelligible language, so that our non-scientific readers will have no difficulty in following the author in his description of the phenomenon of Induction.

In addition to the power of communicating a *charge* by spark or contact, an electrified body exerts a peculiar influence on all conducting bodies near it, which increases if they are made to approach, and diminishes if they are removed to a greater distance, nearly ceasing after a certain limit of distance has been attained. This influence on conductors not in contact is called *Induction*.

When an electrified body is brought sufficiently near an insulated unelectrified conductor, the natural electricity of the latter is decomposed, the electricity of the *same* name (positive or negative) being repelled, and that of the opposite name being attracted; so that, however thin the body may be, even if it be a piece of gold leaf, its opposite sides will have contrary tensions. The induction, strictly speaking, does not take place on the conductor, but on the adjacent surface of the air, or the dielectric which coats or covers the conductor.

Take two insulated plates of metal, A and B, connect each to a separate electroscope; charge A, its electroscope will diverge; bring it near B, taking care that a spark be not allowed to pass



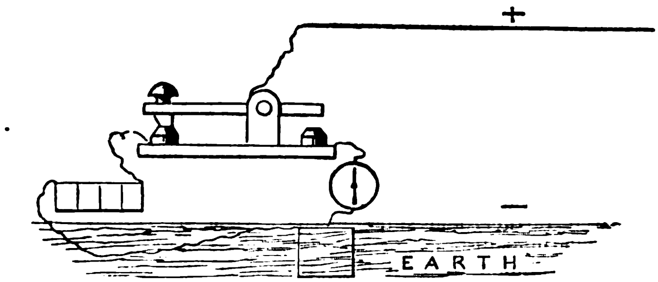
between them, so as to charge B in the ordinary way, the electroscope connected with A will remain divergent, because the plate remains charged, and that of B will diverge, because of the induction exercised upon B by A. Separate the plates, A will remain divergent, but B will cease to show signs of electricity, because the inductive influence of A has ceased. Thus:—if the plate, A, is electrified positively, and made to approach the insulated unelectrified plate, B, its positive electricity decomposes the natural electricity of B, attracting its negative to the side next A, and repelling the positive to the other side of the plate. When A is removed, the two separated electricities of B recombine, and it regains the neutral unelectrified state, while A has neither gained nor lost anything by its action on B. If when the two plates are near each other we touch A, we shall discharge it, and all electrical signs will cease in both plates. If we touch B, instead of A, we shall not discharge A, but we shall remove from B the positive portion of its natural electricity, which has been separated by the influence of A. It will escape to the earth through the finger, leaving B charged negatively. This negative charge will be held fast by the positive charge of A, and will exert no influence on surrounding bodies, so that the electroscope of B will cease to diverge, as if that plate had lost all electrical tension. If we now touch A we shall not discharge it, as we should have done in the first instance, because of the inductive influence of B. In fact, the reaction of the opposite charges in the two plates prevents either being entirely discharged by a single touch, unless both are touched at the same moment. If the plates are removed beyond the distance at which they can sensibly act upon each other, the electroscopes both of B and A will diverge, for the two charges are now free to act on bodies within their influence, and therefore repel their respective pith balls or gold leaves. Either plate can now be readily and perfectly discharged. If they are made to touch, their respective charges will rush together and neutralise each other. If when the plates are very near one another a piece of glass be placed between them, the inductive effect will be greater than when air alone intervenes. A plate of shellac will increase it further, and sulphur will have a still greater effect. Each insulating substance, or *dielectric* as it is called, has a natural power appertaining to itself with respect to induction, which is called its "specific inductive capacity."

A pane of glass coated on both sides with metal foil within an inch of its edge, or a wide-mouthed bottle coated inside and out to within a short distance of its neck, forms a *condenser*. The coated bottle is called a Leyden jar. The foil on the one side may take the place of A, that on the other side the place of B. The condenser is so called because, by its means, we are enabled to condense or accumulate upon a given surface a greater quantity of electricity than it would contain were induction not brought into play. We can also make use of the *specific inductive capacity* of glass, resin, gutta-percha, or other *dielectrics*, still to increase the charge. For as the positively charged plate, A, now represented by the inner coating of the jar, is very near B, represented by the outer coating, the positive electricity of the latter will be repelled, and if B is not insulated from the earth, its positive electricity will escape and the outer and inner coatings will be charged, but with opposite electricities. B reacts on A, so that their respective charges are, as it were, held fast the one by the other. A is then able to receive an additional positive charge from an excited body, which it would not have been able to receive but for the influence of B.

Faraday considers that a current is conducted along a wire by each successive particle undergoing induction, and discharging itself to the next beyond it. The particles of a *conductor* offer very little obstacle to this induction and discharge, so that the current or transfer of force is carried on with extreme rapidity. When the wire is sufficiently near another conductor to be able to exercise an inductive influence upon it, the exterior induction must be completed by each portion of the wire before the current can pass on to the next. This process occupies a sensible time. When the wire is fully charged, it conducts precisely as if there were no induction, so long as the current is steady and regular. If it varies, the induction must be increased or diminished, as the case may be, before the variation can be transferred to the distant end; and when the battery contact is broken, the induction must cease in each successive section of the wire before it is fully discharged. Though induction takes place in curved lines as well as in a direct line, yet it diminishes so rapidly with distance, that the effect is always greatest on surfaces *directly* opposed to one another; thus, though a wire suspended on poles influences the wires near it and the earth, the effect is very slight compared with that of a buried wire. Yet it can be made evident by proper means.

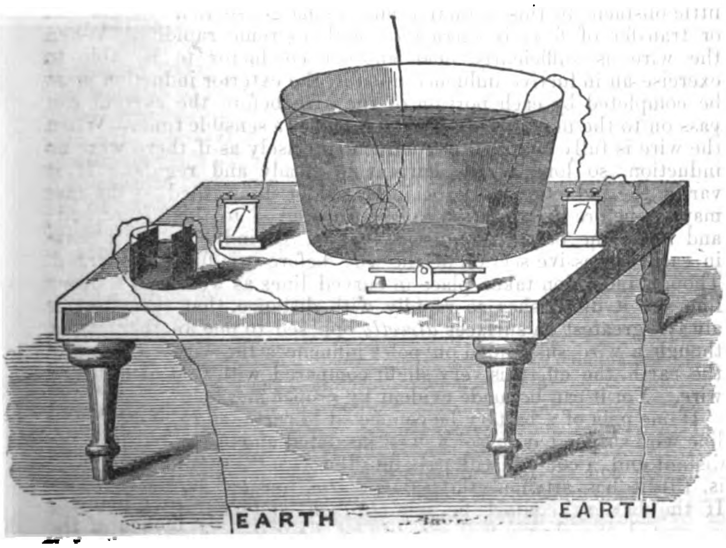
If one pole of a battery be connected to earth, and the other to a line wire suspended on poles, well insulated and *disconnected* at the distant end, a current will pass into the wire till it is charged, that is, till it has attained the same *static* tension as the battery. If the battery contact be now broken, and the wire left disconnected, the charge will speedily be dissipated through the air,

and by leakage at the supports. But immediately battery contact is broken, if the wire be put to earth at the sending end through an electro-magnet or galvanometer, a *discharge* will take place through the apparatus, as when the plates A and B are made to touch one another. If the wire is short, the discharge will be completed before the apparatus has had *time* to move. The time increases with the length of the wire (other things being equal) until it attains sufficient duration to affect the apparatus. For instance:—if the key of a Morse instrument, connected to a long, well-insulated wire, be pressed so as to charge the wire, and be then allowed to fall back very suddenly, the discharge or *return current* will move the relay and produce a signal. When the wire is very long, it is not necessary even that it be disconnected at the distant end, because the resistance is equivalent to partial insulation.



As induction requires time, it tends to limit the rapidity with which signals can be transmitted; for if the effect of one current has not entirely ceased before that of another commences, the signals will "*run together*" and be confused. On half-a-mile of suspended wire 500 or 600 signals may be readily sent per minute; but at a distance of 500 miles the current would appear continuous. By reversing the currents the wire can be discharged more rapidly, and the speed increased. If the line wire were brought very near the ground, the inductive action of the wire and earth would be increased, and the time of discharge increased also; and if it were covered with an insulator and buried, so that the distance were still further decreased, and the wire directly opposed on all sides to another conductor, induction and retardation of signals would be enormously increased, and the discharge or *return current* would be very powerful, because an immense Leyden jar would have been formed, having the wire for its inner and the earth for its outer coating, which being in direct communication with the earth, like the plate, B, when touched with the finger, would part with the electricity set free by induction, enabling the wire to take up an additional charge from the battery. Each mile of ordinary coated copper wire (No. 16) has an inner surface of about 86 square feet, and an outer surface of 330 square feet. A hundred miles of such wire will expose a very large surface.

Mr. L. Clark gives the following illustration in the "Submarine Report," p. 316:—Insulate a large tub filled with water, and place about half-a-mile of percha-covered wire in it. Put one pole of a



battery of 250 cells to earth, connect the other pole through a key and galvanometer to one end of the wire, leaving the other end disconnected and well out of the water. Place a copper plate in the tub, connect it by a wire to a second galvanometer, and put the other terminal of this galvanometer to earth. The water of the tub will thus be put to earth through the second galvanometer. If a charge be sent into the half mile of wire by moving the key, electricity of the same kind will leave the water for the earth. Both the galvanometers will move in the same direction, precisely as if they were both in circuit, whereas the circuit is not completed. There will be this difference:—in the case before us the needles will be affected for an instant only, however long we may press the key, while if the circuit were complete they would continue deflected until battery contact was broken. The water, which is the outer coating of the wire, and which takes the place of the plate B, is put to earth. Hence the portion of its electricity, repelled by the charge given to the wire (or plate A) passes to earth, and an additional quantity passes into the wire from the battery.

If 100 miles of covered wire be placed on a wooden floor, signals may be sent through it nearly as clearly and distinctly as on an ordinary circuit of the same resistance. But if it be put in water, one end insulated, the other end connected through an ordinary needle instrument to earth, and a battery of 40 or 50 cells joined to the instrument, then, if the key be moved as if to send a signal, the needle will be violently deflected for an instant, by the current entering the wire to charge it. As soon as the wire is charged the needle will regain the perpendicular, although the key is still held in the position for sending a current. If the handle be placed upright so as to cut off the battery and put the wire to earth, the needle will again be violently deflected, but in the opposite direction, by the charge escaping from the wire.

Now, if the wire had been lying on the floor instead of in the water, the needle would scarcely have moved, however powerful the battery; for though a current would enter into and charge the wire in this case also, the effect would be slight, and last too short a time to do more than barely move the needle. Similar effects will arise if the wire is connected to earth at the distant end, but they will be less marked.

If two lengths of 100 miles, or more, be placed on a dry floor, and if a needle instrument be inserted between each length, and one at each end, so as to form a circuit, when signals are sent in the usual manner, all the needles will move sensibly at the same time, sharply and distinctly. But if the wire be put in water or buried in the ground, and the circuit be completed through the earth in the usual way, the needle at the battery end will move immediately the handle of the instrument is turned; the second needle will not move at the same instant, but a perceptible time afterwards; the third needle later still; and so on, showing the current now travels more slowly than before. When the handle is caused to break battery contact and put on the earth, a discharge will take place, and the needles will fall back one after the other, commencing with that at the battery end.

The practical effect on a needle circuit is this:—the sending needle is jerked violently in the reverse direction after each signal, and frequently becomes demagnetized, or cross magnetized by the discharge or return current. The receiving needle moves sluggishly, and the signals run together, so that a letter of three movements appears like one of a single movement sent slowly. Signals through buried wires are thus seriously retarded.

On a printing circuit the marks run together, each dot being lengthened by the discharge of the electricity "pent up," as it were, by induction.

Reversing the current facilitates the discharge at the sending end, by neutralizing the charge with electricity of the opposite name, so that there is not so much to escape at the receiving end. This renders the received signals much more distinct.

When a covered wire is coiled into a regularly formed bundle, especially if it be wound upon an iron drum, the discharge at the sending end is in the same direction as the current entering the wire, instead of the opposite direction. By some it is supposed that this is caused by the *induction of a current on itself*, causing a prolongation of the flow of the current in the wire after battery contact is broken. On a short length this is stronger than the "return current," and overpowers it; therefore the return current in a coiled cable *appears* to be in a different direction to that in the same cable when laid out straight. Mr. C. F. Varley considers this to be purely a magneto-electric phenomenon.

In testing a buried wire, or even a well insulated suspended wire, the distance of a disconnection may be estimated by the amount of the return current; for the longer the wire the longer will be the time occupied in the discharge, and the greater its amount. If two or three successive currents be sent into a long buried wire, they will travel on independently of each other. It is even possible to produce alternate waves of positive and negative electricity, that is, to charge the two ends of a wire oppositely.

A cable, coated with iron wire, is subject to a large amount of induction, even when out of the water, because the iron covering is a good conductor. When coiled, the induction of the current on itself is increased by the reaction of the magnetism set up in the iron coating.

A spark may be obtained by making and breaking contact between a battery and an electro-magnet, or even a spiral of wire, when the wire forming them would give no spark if stretched out straight. This increase of effect is due to the same cause as the difference in the direction of the discharge in a coiled cable from that in one laid straight.

As a wire, even when most free from inductive retardation, takes a certain time to charge, the current will not attain its maximum strength till battery contact has lasted sufficiently long. The more faulty the insulation, and the longer the circuit, the more firmly and slowly must the battery contacts be made.

THE INTERNATIONAL EXHIBITION, 1862.

(*Continued from page* 257.)

9. *Induction Coils.*

Siemens & Halske, Berlin, M. (Prussia, 1,413), exhibit the finest induction coil shown. Every detail connected with it has been made the subject of accurate experiment, and the results obtained are well worthy of attention. They have kindly sent a description, of which the following is a free translation:—

This instrument consists of a core of iron wires, each 1·3 millimetres in diameter, and 95 centimetres long. These are cemented together, and form a cylinder of 60 millimetres in diameter. Two layers of copper wire 2·5 millimetres in diameter are wound round this core; the primary coil and iron core weigh together 35 lbs. They are placed in a tube of hard vulcanized india-rubber (ebonite), which is 26 millimetres thick at the ends, and 12 millimetres in the middle. Along this tube 150 thin discs of ebonite are fastened at equal intervals, and the two ends are covered with thick discs of the same material. Each subdivision between the little discs is filled with a coil of fine silk-covered and varnished copper wire 0·14 millimetres diameter; these coils are so connected as to form one continuous secondary coil, in which the current will run from inside to the outside of one compartment, but from the outside to the inside of the next. By this device no two portions of wire at greatly different potentials are ever in close proximity, and consequently the risk of injury to the coil by its own current is greatly reduced.* The length of the secondary coil is 10,755 metres, and it makes 299,198 turns round the cylinder. The weight of the copper wire is 58 lbs., and its resistance 162,000 of Siemens' mercury units. The resistance of each of the two layers of the primary coil is 32 of the same units.

The insulating tube is made thicker at the ends than at the middle, because the electrical tension is much smaller in the middle, and under normal conditions is even nothing, but gradually increases towards the two ends, so that a disruptive discharge to the iron core is only to be feared towards the end. Another reason is to be found in the fact that the layers of the secondary coil nearest the tube form together with the tube and the primary coil a sort of Leyden jar. The capacity of this Leyden jar should be kept as small as possible, since otherwise the electricity developed by the iron core is held condensed, and the striking distance of the sparks considerably diminished. Now, since in the middle the tension of the secondary wire is null, no unfavourable condensation occurs at that point, and therefore the secondary and primary wires are here brought as near as possible. The best form of the tube is that in which the longitudinal section of its outer surface forms a parabola. Messrs. Siemens use a make-and-break apparatus in connection with this coil, which is set in motion by a barrel-spring; the contacts are made by a platinum point and a platinum or a silver amalgam covered with alcohol. This apparatus is driven quite slowly when long sparks are wanted; the contact is continued for a long time, and very suddenly broken by a small cam which lifts the platinum point.

A spark of from one to two feet in length can be obtained between point and plate with six large Grove's elements. The two layers of the primary coil are used in multiple arc when the number of elements is less than six, and in series when larger than six. This instrument is especially remarkable from the great length of spark obtained with a comparatively very small length of wire in the secondary coil. In fact, this length does not exceed 6¾ miles; whereas other induction coils have required 50 miles to give similar results.

W. Ladd, London, M. (United Kingdom, 2,925), exhibits induction coils, from which he obtains five-inch sparks, using five cells of Grove's battery, with plates five inches by three inches immersed. The construction is as follows:—On a core of iron wire about a foot long are wound fifty yards of copper wire of No. 12 B.W.G. (·034 inches) insulated with cotton; this coil forms three layers, round which five or six thin gutta-percha sheets are wrapped. The secondary coil, formed of three miles of No. 35 copper wire (0·005 inches) insulated with unvarnished silk, is wound backwards and forwards along this core, with each layer insulated from the preceding one by five or six sheets of thin gutta-percha.

Mr. Ladd also shows a coil of very different proportions; the iron core and primary coil are about eight inches long, but the secondary coil placed in the centre of its length is only four inches long, but seven and a half inches in diameter. Much the same results may be obtained with this as with the preceding coil.

Mr. Ladd's "make-and-break" for the coil is very simple, but apparently effective. A soft-iron armature is carried by a spring in front of an electro-magnet. The reaction of the spring can be strengthened or weakened by a set-screw. When the reaction of the spring is weak, the coercive force of the electro-magnet retains the armature for some time after the current ceases, so that some time lapses before it flies back again to make contact, and when contact is made it is immediately broken; when, on the contrary, the spring is strong, the current hardly ceases before it is re-established, and is not again broken until the electro-magnet has reached its full strength. This simple plan allows the number of contacts per minute to be readily regulated, as well as the proportion between the make and break.

As already mentioned, Mr. Ladd exhibits a great variety of vacuum tubes for use in connection with his coils, to demonstrate the various phenomena of the "striated electric discharge" that have been so elaborately investigated by Mr. Gassiot. He also exhibits two apparatus that deserve notice from their singularly beautiful results. One of these, the *electric cascade*, consists of a glass vase placed under the receiver of an air-pump, down to the bottom of which one of the electrodes is carried, the other being connected with the plate of the air-pump. When the plate is negative, the current appears to flow out of the vase in a single stream; but when it is positive, the vase is surrounded by a glow, and if made of glass coloured by uranium, is brilliantly illuminated by fluorescent light. In the other, the discharge is made to pass along the surface of a glass tube in an exhausted receiver. When a cylindrical bar magnet is introduced into the glass tube, and the receiver sufficiently exhausted, a stream of light will be observed to rotate round the magnet.

A. Rasmussen, Copenhagen, H. M. (Denmark, 152), exhibits an induction coil for medical purposes, in which the primary circuit may be made and broken either by the common trembling hammer or by clockwork driven from a barrel spring. By means of the latter, longer or shorter contacts can be made at will.

* Mr. C. F. Varley has shown the writer a description of this method of winding the secondary coil in a patent taken out by Mr. Varley in 1856.

Considerable numbers of induction coils for medical purposes are exhibited; they are generally arranged with considerable ingenuity, with various means of altering the number of shocks per minute, and their strength.

A. Moreau, Paris (France, 1,443), exhibits a large collection of highly-finished induction-coil machines for medical purposes; they do not, however, present any peculiar features of construction that require special notice.

10. *Miscellaneous Philosophical Instruments.*

Siemens, Halske, & Co., M. (United Kingdom, 2,959), exhibit an electric resistance thermometer, in which the change of resistance which metals undergo, with a change of temperature, is made use of to indicate the temperature of the metal. Two perfectly similar coils of insulated wire are enclosed in two hermetically-sealed copper cases. One is placed on the spot of which the temperature is required, and the other in a bath of water; the temperature of the bath is altered until the resistance of the two coils is exactly equal, an equality which can readily be tested by a differential galvanometer. The temperature of the bath will then clearly be equal to that of the spot where the first resistance coil is placed. The connections are made with very thick copper wire, so that their resistance shall have little or no influence on the result. The wires are coiled on an open copper cylinder of considerable diameter and length, so as to expose a large surface to the air or water in which they are placed. They in consequence take the temperature of the surrounding medium with great rapidity. This instrument will be found useful for determining the temperature at different depths in the sea, and other similar purposes. A similar idea was made use of by Svanberg for some experiments published in Poggendorff's Annalen for 1851.

The Telegraphen Werkstätte of Berne (Switzerland, 151) exhibit an "electric self-registering thermometer." This instrument is an application of Bréguet's metallic thermometer. Two metal strips, brass and steel, are soldered together and bent into a spiral, the inner end of which is fastened to a brass standard, while the outer end carries an index with a steel point, used to mark the registering paper. Two brass rollers, one of which is connected with a ratchet-wheel, unroll a wide strip of paper about 130 metres long, and pass it under the steel point. An electro-magnet and armature are used to mark the paper; a momentary voltaic current is sent round the magnet at fixed intervals (every twelve seconds in the Observatory of Berne) by a clock with suitable contacts; a lever fixed to the armature strikes down the end of the index at the moment when the current passes, and so prints a dot on the paper; when the current ceases, a paul fixed to the armature moves the ratchet-wheel one tooth forward, carrying the paper along with it. Two millimetres on the paper are equivalent to one degree centigrade. A little fixed wheel impresses a straight line in the centre of the strip of paper, from which the deviations of the curves formed by the dots can be measured.

M. Hipp, Neufchâtel, M. (Switzerland, 156), exhibits an electric current regulator, intended to maintain a nearly constant current, and designed for use in connection with electric clocks.

The mechanism consists of two electro-magnets, the armature of one of which works the pointers of the clock, while that of the other is used to increase or diminish the resistance of the battery circuit when any variation occurs in the strength of the current. This is done as follows:—A standard clock makes and breaks contact at regular intervals in a circuit containing the battery and two electro-magnets, one of which works the propelment of the secondary clock. The armature of the second has two springs attached to it pulling it away from the magnet. These two springs are so arranged that if the current passing is weaker than it should be, the armature will not move either of the springs; if the current be exactly that required, the attraction of the armature will overcome one of the springs, and the armature will be attracted to a half-way position. If the current be too strong, the armature will be attracted close to the magnet, overcoming the two springs. Now the gearing is so arranged, that an index will be moved round by the wheelwork propelled by the first electro-magnet, when the armature of the second is in its furthest position, but will be left at rest when the armature is in its second position, and will be moved backwards when that armature is in its third position. The index in its motion turns resistances in or out of circuit, according to the direction of its motion, until the current is reduced or increased to its proper strength.

Electric clocks and other instruments of the kind may be worked with greater certainty and economy, and with less superintendence, by the constant current which is thus obtained, than with the usual variable current; the battery also lasts longer; nor is it necessary to begin with an extra strength of battery, allowing for a gradual diminution of strength; a single glance at the index shows the condition of the battery, and warns the superintendent when it must be replaced by a new one.

Elliott Brothers, M. (United Kingdom, 2,897), exhibit some very delicate and sensitive thermo-electric piles, composed of small bars of bismuth and antimony, for use in connection with Melloni's and other apparatus employed in investigations on heat. Their construction, although not novel, is excellent.

V. PRACTICAL APPLICATIONS OF ELECTRICITY OTHER THAN TELEGRAPHIC.

1. *Electric Clocks.*

Electric clocks have not been so extensively adopted as might reasonably have been expected from the excellent examples shown in 1851. Nevertheless, a considerable number are again exhibited, and those which contain any novelty of importance will now be mentioned.

The British and Irish Magnetic Telegraph Company, M. (United Kingdom, 2,864), exhibit Jones' electric clock. Clocks worked by electricity have hitherto either been driven by the galvanic current or regulated by the release of an escapement. In all these plans, if the battery gets out of order, if the communicating wire is broken or badly insulated, or if any of the contacts are defective, the clock stops altogether; and it is probably this very serious defect which has hitherto limited an application of electricity which at first sight appeared to offer very considerable advantages.

Mr. Jones' plan consists in simply checking any irregularity of beat in the pendulum of clocks to be controlled by a current passed from the standard controlling or regulating clock, through coils forming part of their pendulum bobs. Permanent magnets are fixed on one or both sides of the centre of the arcs of vibration of these pendulums, and the current, at the moment of its passage, influences the position of these pendulums relatively to the fixed magnets. If the pendulum approach the extremity of its arc of vibration a little behind time it is accelerated, if a little before time it is retarded. The current sent by the regulating clock may vary in strength within very wide limits, but only a feeble current is absolutely necessary, since the amount of correction required at each beat is in every case very small indeed. The current acts solely as a corrector of errors, and should any of the above-mentioned accidents occur to interrupt it, the controlled clocks will not stop, but will simply keep their own time independently, until the current is again passed. Thus Mr. Jones' method effects all that can be done by the most perfect and delicate systems of electric escapements, and at the same time entirely avoids the risk of failure inseparable from even the best of these plans. Moreover, it requires no accuracy of construction, and might be applied to almost any form of clock. Mr. Jones' clock is specially mentioned with approval in the award of a medal to the British and Irish Magnetic Telegraph Company.

L. C. F. Bréguet, Paris, M. (France, 1,413), also exhibits a plan for the regulation of clocks by electricity, which successfully meets the above-mentioned difficulties, and has many of the same merits as Mr. Jones' invention. M. Bréguet, instead of correcting all his secondary or controlled clocks once a second, or once at every beat of the pendulum, corrects them only once every six or twelve hours, by then bringing the minute hand exactly to the hour point. This is done in the simplest manner by a little train of wheels driven from a barrel spring, and set free by an electro-magnetic detent at the moment of correction; two small cams, one on each side of a projection connected with the minute hand, are turned once round by this train of wheels; if the minute hand be behind its time, one of these cams moves it on; if it be before its time, the other cam moves it back. This method is simple and effective where no extreme accuracy is required between the long intervals of correction. It moreover avoids the difficulty of making good contacts from the pendulum of the standard clock without some injury to its time-keeping qualities, a danger which Mr. Jones' method does not provide for.

The Universal Private Telegraph Company [Professor Wheatstone, Juror] (United Kingdom, 2,978), and W. T. Henley, H. M. (United Kingdom, 2,908), exhibit fine examples of the old form of clock, in which the escapement is worked by currents received at regular intervals from a standard clock.

T. Van Spanje, Tiel, H. M. (Netherlands, 186), exhibits an

electric clock driven by a ratchet propelment worked with intermittent currents passed from a standard clock through suitable electro-magnets. The propelment is peculiar in having a separate star-wheel on the same axis as the ratchet-wheel. The arm which carries the propelling pallets also moves two stops, which, at the end of each oscillation of the pallets, bring the axis to a dead stand by coming against a tooth in the star-wheel.

M. Gloesener, Liége, M. (Belgium, 349), exhibits a clock with an escapement worked by reverse voltaic currents; he appears to have been one of the first to perceive the advantages to be derived from the use of reverse currents, as opposed to single currents separated by an interruption or an earth contact.

J. H. Koosen, Pirna (Saxony, 2,330), exhibits an electric clock, which is not driven or controlled from a standard or primary clock, but is entirely independent, and keeps time without the aid of a pendulum. It consists of an electromotor of simple form and a regulator. The electromotor used to drive the train of wheels does not require special description. The speed is regulated by a centrifugal governor, so arranged as to interrupt the electric circuit in the electromotor whenever the required speed is exceeded. The centrifugal governor is so disposed as to be extremely sensitive to small variations of speed. The force of a spring is made use of, instead of the force of gravitation, to restrain the centrifugal force of the governor balls, and this spring is so adjusted with reference to the rotating mass, that the slightest excess of speed above that required causes a great deviation from the axis.

It will easily be seen that, with a sufficiently powerful current, the wheelwork will be driven at a sensibly uniform speed, for the current will be continually interrupted by the governor, and only admitted into the coils of the driving electro-magnets for just such a fraction of each minute as will keep the governor on the point of breaking contact. It is to be regretted that the instrument exhibited was so much injured in transit that it could not be put to work. One obvious drawback to the system is the oxidation of the contact points by the strong sparks which must continually pass as in a relay.

Several other examples of electric clocks were exhibited in Class XV. by T. Dettmann, London, H.M. (United Kingdom, 3,246); C. G. Gumpel, Brixton, H.M. (United Kingdom, 3,256); W. Morris, Blackheath, H.M. (United Kingdom, 3,285); C. Shepherd, London, H.M. (United Kingdom, 3,307); A. Müller, Lôcle, H.M. (Switzerland, 218).

(To be continued.)

METEOROLOGICAL RECORDS.

Vice-Admiral Fitzroy has recently published the result of his observations for the past year. The report is addressed to the President of the Board of Trade. Although we for the present only quote a notice of the report which appeared in a contemporary, we intend to refer often to the subject matter of the report:—

"During the time that has elapsed since my last report, experience has brought the natural result of improving our recently-acquired knowledge of atmospheric changes, and giving more confidence in drawing conclusions. Demands have increased for cautionary notices of strong winds, such as would affect the smaller and less efficiently provided vessels, or when increased to gales, if not to storms, might delay, injure, or occasion risk even to well-found ships. Not only are such notices sent day by day regularly to Paris for the French coast, but occasionally to Hanover, and to other places near the North Sea, in consequence of special applications made by foreign Governments. Italy is adopting the methods of weather warning originated at our Board of Trade; and no less than twenty-six stations are intended to be formed under the direction of Signor Matteucci, with a committee, at Turin. While adverting thus to forecasts and cautions, it should not be supposed that these new and immediately practical consequences of this Board of Trade branch office have superseded, or in any degree injured, duties intended to be carried on when first the department was organised (in 1854-5), soon after the Brussels Conference of 1853. In ten years an accumulation of valuable log-books, observatory registers, and miscellaneous records has been effected here. Many years must elapse before these stores and those of the Admiralty (at Somerset House) can be so nearly exhausted, that more supplies of facts than those still continually added, as selected ships arrive, may become requisite. Since 1856 all the logs of her Majesty's ships have been kept in an uniform and well-designed manner; while a supply of good instruments has been available for each ship, and directions have been issued to officers by the Admiralty on the subject of observations; therefore, now an immense amount of good records in naval logs, in addition to the remark-books and surveyors' registers sent to the Hydrographic-office, is available in London. A very large body of facts relating to the atmosphere and ocean, valuable in proportion to their number (being alike accurate), are almost ready for publication; but as a few more may yet be advantageously added to each series, I am reluctant to give them the last notes until able to do so more satisfactorily. In my last report I stated how highly the Board of Trade 'fishery' barometers have been valued on the coasts. They are now eighty in all, specially lent under due control and care. It may be more readily estimated mentally than accurately proved to what extent these simple instruments (all reliably made by Messrs. Negretti & Zambra and tested) have already been the means of saving life and property. Explanatory manuals and blank forms for diagrams have been extensively circulated among the coasters and fishermen, who are all now much influenced by, and very thankful for, the benefits of this act of their Government. Many are the local instances of similar beneficence by individuals, especially the Duke of Northumberland, who has placed no less than fourteen barometers.

"By knowing the statical conditions of atmosphere at several places simultaneously, and again similarly after certain intervals of time, comparisons can be made which show causes of fluent (or dynamic) effects, not unlike those of a head of water acting on a stream, though complicated by the peculiarities of air—in some qualities so different from any liquid. Such atmospheric currents are our winds, softly gentle or increasing to a tempest—powerful in places as a discharge from a gigantic air-gun, or a great explosion. Instrumental means and telegraphy now enable such changes to be made known for many places, if not for all localities, within a certain limited circle of climate—about five hundred miles in radius—where land and water are intermixed, but probably a thousand miles over uninterrupted ocean. It may now be asked—What is our actual degree of acquaintance with atmospheric changes and their indications? In answer, I submit that our knowledge is already sufficient for practical purposes, and may be communicated to a fairly-educated and able person. Ability and due preparation are, of course, as indispensable as for other results of study and practice. That we have proved experimentally how winds and weather may be foretold with general accuracy for two days at least in advance, our reports since 1861 have showed—if insufficiently at first, certainly to the satisfaction of a large majority at present. That we are acting on true principles our results leave not a doubt on my mind (and in stating this, I may be pardoned for alluding to unintermitted attention to meteorology, which special avocations, in all oceans and at many places on land, have induced during forty years of observation). But to act judiciously, with sufficient rapidity, on even unerring principles, is and must ever be more or less difficult.

"It has been asked—'If you are absent, who carries on the responsible duties of forecasting, and giving cautionary notices when necessary?' My reply has been to the effect that an assistant is fully acquainted with the subject, and has not only executed these very duties often during the last two years, but has done so generally since last autumn, occasionally relieved by me, to whom he refers at times, though now but seldom. Besides ourselves, there ought to be two or three in training for these special duties—now systematically established. Often a hasty reply, an off-hand opinion, an injudicious or unqualified answer has been given, and incorrectly, without reference to the forecasts elaborately drawn with deliberation—whence a deserved degree of blame has resulted. But such a discrepancy has been caused by individual error, not by a failure of the system."

ON THE PATENT LAWS.

Discussion.

(Continued from page 262.)

Mr. Winkworth said that he had intended to enter, at some length perhaps, into the discussion, but his friend Mr. Hawes, in his admirable speech on Wednesday last, had so fully anticipated any arguments he could have adduced in support of the views they held in common on this subject, that he would content himself with a few words only. Having about ten years since, on the occasion of a paper on the patent laws read by Mr. Webster—distinguished like that with which he had favoured the Society at their last meeting, by acute reasoning, if not by conclusive arguments—taken a rather prominent part in the discussion, he could not reconcile it to himself to be quite silent that evening. Although in the debate to which he referred only one other member besides himself, Mr. Denison, advocated emancipation from the paralysing influence of these laws, it was spread over no less than three meetings. Either, therefore, the arguments they had advanced were very cogent, or those who adopted the views of Mr. Webster, being themselves inventors and too much dazzled by the prizes which they saw dangling before them, were too much interested in the retention of the law to see clearly that the statements they made of the hardships imposed on inventors by these laws, were precisely those which established their utter worthlessness. For his present purpose it was not necessary that he should affirm or deny that invention or discovery, when published, was property, but it must be borne in mind that such publication was voluntary and not compulsory. All that he argued was that in the interest of progress in art, science, and manufactures, even in the interest of humanity itself, these laws ought to be repealed. Since the time alluded to above, other and more important opponents of these laws had entered the field: it was sufficient for his purpose on the present occasion, though there were many

others whom he might name did time permit, to refer to the late eminent engineer, Mr. Brunel, who, in the chair, when Mr. Hawes read a paper on "the Soap Manufacture," eagerly availed himself of the opportunity to confirm Mr. Hawes's complaint of the impediments to improvement which these laws presented at every turn, and to condemn them from dear-bought experience. In fact he denounced them in the most emphatic language, as having been a constant source of annoyance, difficulty, and loss, the full extent of which it would be difficult to exaggerate. In this he (Mr. Winkworth) fully concurred, and nothing had taken place since that time to alter his conviction that these laws were not susceptible of improvement, and so long as any similar enactments, professing as these did to encourage invention, were suffered to continue in operation, the complaints so frequently repeated during this discussion in various forms, would be urged by the sufferers from them. He need scarcely add that the views he had long entertained were confirmed by the discussion, so far as it had gone.

Captain SELWYN, R.N., said, as a member of the Council of the Inventors' Institute, he felt it would not be well if the discussion were allowed to be closed without expressing the opinion of that body. They felt it to be their mission to protect the interests of inventors, and he was there to say distinctly, that although there might be defects in the present system, and although the laws might be very faulty, and the interests of inventors and the public might appear to be antagonistic, this was not really the case. The first question started by Mr. Webster was, whether inventions should be encouraged and inventors rewarded. No one could have attended the discussions which had taken place without seeing that the general sense of the meeting was to affirm this proposition. He did not see the good of having a board of experts, for his experience of boards had taught him that, if parties applied to boards, they were sure not to get anything done as long as there was any possibility of anything being staved off. He did, however, rely on one board, and that was the public. The public was the great body of experts who seldom or never made an error, and who gave a really practical decision on a patent by giving money for it, and in that way the inventor was very fitly and properly rewarded. But few of the inventions which are brought forward would ever be carried out successfully, if the whole energies of one individual were not devoted to that single object. There had been something said about injustice to the public and the manufacturer. The manufacturer was not obliged to buy an invention, and if he bought a patent and found himself taken in, he had no more right to complain than a man had who had bought a horse without a warranty, and then had found it to be unsound. If he acted on his own judgment, without making proper investigation, he must not be surprised if he was duped. He thought they should never pull a brick out of any structure without they had a better one to put in, and in this case that had not been brought before them. Certainly it had not been brought forward at this meeting. He entirely denied the argument which had been used in connection with the copyright law, and he thought that the manufacturers had not spoken of inventors in the way in which they should, because it must be remembered that it was the inventors who had made the manufacturers what they were, and who had made our great nation what it was. But for them, mankind would now be in much the same condition as they were in the time of Adam. No doubt such men as Sir William Armstrong and Mr. Hawes were in positions which rendered them independent of the patent laws, but he could not conceive of any engineer, mechanic, or artizan, wishing to do away with such a stimulus to exertion and improvement.

Professor WANKLYN wished to correct a remark of one of the speakers, who said that patent laws existed throughout the whole of Europe. There was certainly one place where there was no patent law, and that was Switzerland, and, indeed, throughout a great portion of Germany there was virtually no patent law, for everything had to be patented some thirty or forty times before a patent became valid. According to this it would appear that there was at least one part of the civilized world where patent laws were in disrepute. He would just say one word as to why patent laws should be abolished. The justice due to inventors was often insisted upon, but why was it just to reward an inventor? Only as an example of this great principle—that it was just to reward individuals who conferred great benefit upon society, but who reaped no reward themselves. Now, was this practicable? Could we do this? He thought it was utterly impracticable. There were a great many people besides inventors who conferred immense benefits upon society, but who themselves reaped no rewards. If, then, there was no other argument for the law than that general principle, it must fall at once, because if once they admitted it, it would lead them too far. He would give a very common instance as an illustration. Everybody knew now-a-days of the immense improvements which had been made in the production of dyes. Dyes had been produced, as everybody knew, from coal tar. In the production of these dyes about a hundred people had been employed in order that this end might be produced. What did the patent law do? Why, it did not confer any reward upon any of those hundred people, but only just upon the last man, who appeared to put the last stone to the edifice which others had raised. Now was this just? Why should they single him out, and pass over all the others? The system was an unjust one, and he believed there was nothing in this country so unfavourable to science as the patent laws.

The CHAIRMAN said he thought the meeting would agree with him that the subject had now been sufficiently discussed to make it right that he should ask them to do what he was sure it would be very gratifying to them to do, to express their thanks to the author of the paper, who would be afforded an opportunity of making observations in reply to some of the arguments which had been addressed to the various questions raised by his paper. He should like, however, with the permission of the meeting, to make a few observations upon the subject matter of discussion, before he conveyed their thanks to Mr. Webster for the paper which he had read. He thought it was very fortunate that the subject had been introduced by a man who had himself had so much personal experience in the working of the patent law, and who had had a large share in the framing the patent law of 1852, or at least in the combining of two bills into one Act of Parliament and who since that time had had great experience of the working of the Act. He would not, however, consider the merits or demerits of the Act of 1852, which regulated the forms of precedure necessary for acquiring patent rights, but would limit himself to an inqniry into the claims of inventors to some public recognition. With the exception of one or two gentlemen, there had been but little disposition to deny the claims of men who had invented important improvements in manufactures to some kind of recognition. He thought the general objection had been rather to the form of recognition by means of the patent law. If it were fitting to reward intellectual results in the form of inventions, or of works of literature, or art, the question then arose whether the protection of inventors for a limited period of time was a reasonable character of reward. They knew that there had been in this country, and doubtless in others, some subjects for which the State had offered rewards, such, for instance, as the important discovery of the longitude at sea, for which a State grant was made to Harrison. Then again, there was the north-west passage, which the State thought of so much importance that its discoverer would be deserving of a large national reward, and although the State by these acts had recognised the right of reward for great services, it was obvious that with regard to the greater number of inventions such a mode of reward was utterly inapplicable. It had been said by some gentlemen who did not deny the right to a reward, that it would be better to give that reward out of some public fund. He thought, however, that the greater part of the meeting would adopt the views ennnciated by Captain Selwyn, that, however desirable a public board might be to decide as to the novelty of any particular invention, the public were after all the best judges. No public department could successfully accomplish the desired object, so that they were brought back to the system already adopted in this and other countries. It seemed to be considered that whether in connection with literature, science, art, or invention, protection of the inventor was the most convenient, the justest, and the best reward which could be bestowed upon him. All that was done was that, for a limited time, he was allowed the use of his invention before the general public could have the benefit of it. He could not himself see what injustice there was to the public in that. He would refer them to statute of James I., and ask them if the words of the statute could be improved; and when it was said that this law was a relic of the olden time, it must not be forgotten that America adopted the principle of it in 1790; and that in 1791, at a time when privileges were not very much upheld in France, it was also adopted by that country, and since that time the same principle had been introduced into other countries. The words of the statute, which was for awarding monopolies, were, that it should not extend to letters patent for the term of fourteen years for the sale, working, and making of new manufactures, which shall be "neither unjust, mischievous to the State, nor hurtful to trade, nor generally inconvenient. Could there be a better definition of what the public should reward than that? Something had been said about the patent law being injurious to free trade, but it seemed to be forgotten that all the greatest political economists of our country were in its favour, Adam Smith, Bentham, and John Stuart Mill; and, therefore, when gentlemen talked about its being in opposition to free trade, and looked upon those who supported it as being still in ignorance of sound economical principles, they might be fairly answered that opinions coming from such men as he had just mentioned were at least worth consideration. He would also ask those gentlemen to remember that all the existing laws of copyright had been passed in the present reign, and that only two years ago this very society, by its own laborious efforts, succeeded in getting an act passed for giving artists a copyright in their works, so that this species of protection was not such antiquated legislation as some people described it to be. Then it was said that the present system was unjust to inventors; but he would rather let the inventors determine that question for themselves, and they certainly seemed to be satisfied with the principle of the protection afforded to them, and to desire to preserve it. The gentleman who spoke last had complained that under the present system one was rewarded while another was not, but he was very much afraid that that would be found to be the case in all things in this life. Then the question remained whether it was an injustice to the public that an invention upon which a very large amount of time, and labour, and capital had been expended should be preserved to the use of the inventor for a certain time before the public had the benefit of it. It certainly seemed to him that to defer for a time the enjoyment by the public of the fruits of intellectual labour, employed in important experiments, producing discoveries of much value, was not unjust to the public, and did not obstruct economical progress, and this plan possessed the recommendation of graduating the reward by the extent to which the invention was usefully employed. He would only add that the wondrous extension of our manu-

factures and commerce during the last ten years would seem to show that, whatever other effects might have resulted from the law of patents, it had not hindered the growth of national wealth. He would now, in the name of the meeting, express to Mr. Webster their warmest thanks for the able paper which he had read, a paper which was exceedingly moderate in its tone, and which had therefore brought the subject before them in the best form for consideration.

Mr. Webster said he felt very thankful to the meeting for the way in which they had received the chairman's proposal of a vote of thanks to him, and he would take the opportunity which was now afforded him of making a few observations on some of the points which had been raised in the discussion. He would say at the outset that he really felt very great satisfaction in bringing this subject before the Society, and he believed that much good would result from the discussion which had just taken place. The discussion was certainly a very exhaustive one, and there was hardly a single point which had not been raised. There was no doubt at all that there were very great inconveniences in the present patent law system, and the cost of litigation itself in connection with it was a scandal to the country, though he admitted that this was a matter with which a strong hand could deal. He would not go into detail on legal matters, but there was one point to which he would just refer, and that was that it had been decided that the user of a machine under any circumstances might be liable. That decision, however, had been doubted by a very great authority, and he thought that it was a matter which ought to receive very serious consideration. There was also another question, as to how far a person who was merely the possessor of a patent ought to have the privileges of a patent law extended to him. They all knew how the matter had been dealt with by the present Lord Chancellor; but these were questions which deserved the greatest attention, and if the suggestions which had been made during the discussion were carried out, it would certainly be a step in the right direction. He could only repeat what he had said before, that he did not believe it was expedient to grant patent right as a matter of course. Lord Stanley, in a discussion which was held some years ago, stated that he conceived the only patent right was a right to bring an action, which right should not be granted as a matter of course; and if this were more borne in mind, much of the present opprobrium would be removed. With regard to the appointment of a tribunal for adjusting the rights of the public and of the inventor, there was no doubt that it was a matter of extreme difficulty, and he thought that Sir Edward Belcher and Captain Selwyn had really disposed of that question, and he himself believed that it was impossible for any board of experts to value an invention, which was a matter to be left to the public alone, and then, after the public had valued it, they would find men coming forward to purchase it at its value. He was very glad indeed to see their old friend Mr. Macfie, who had been for so many years a staunch opponent of the present system, though not of the rights of inventors, because he must do him the justice to say that, although he had spoken very strongly on the subject, he had yet always been the consistent advocate of licenses. With regard to what Mr. Winkworth had observed about what Mr. Brunel had said as to the soap trade, he only wished that Mr. Brunel were present, and then he would have asked him which he had found to be the greatest obstruction to the soap trade, the excise or the patent laws. There, in the excise, they had an instance of the most scandalous abuse in restricting invention. It was almost blotted from the statute book, and he hoped that it would soon be abolished altogether. Another topic of some importance had been referred to by some of the speakers, one of whom had asked whether, in order to prevent the taking out of a patent by some one else, he was to advertise his invention in the newspapers? No, certainly not; but he could do this: on the payment of a small fee (and he wished it were less) he could record his invention at the Patent Office in the shape of a provisional specification. That was one of the objects of the new patent law, to provide a means of recording inventions. It was no doubt a very great hardship for a man to make an invention, and after a time to abandon it, and then find afterwards that somebody else had taken out a patent for the same thing, and that he could not use his own invention without being put to a great deal of trouble and expense in litigation. It must be remembered, however, that the patent law did not so much reward the inventor because he was an inventor, but the man who gave the public the benefit of the invention; and this was recognised in the fact that patents were granted to the importers of inventions, the policy of which entirely rested upon this principle, that this was for the good of the public, and for that reason the man was rewarded, and not for being the successful inventor. If the matter was looked at in this view, it would be seen that it was out of regard to the public benefit that the reward was given. Professor Wanklyn seemed to conclude that, because science was not rewarded as it ought to be, therefore the practical arts, as developed in inventions, ought not to be rewarded, but that certainly was no valid argument against the system. He wished the meeting particularly to bear in mind the distinction which he had pointed out the other evening between an inventor and a discoverer, and he utterly denied that there was any analogy between the cases at all. With regard to preliminary examinations, there was a great difficulty in knowing what one single step might lead to, as an inventor was very often before his age. He had referred, in his paper, to the fallacies into which some persons fell in connection with this subject, and he thought that Mr. Hastings had fallen into an entire fallacy in what he had said about territorial grants, because the fact was that it was altogether a false analogy. In the matter of discovering a new country it was entirely a question of first occupancy, which was the basis of all holding of property; that was merely discovering what was in existence before; but in a patent a thing was created which did not before exist, and for that a reward was given. An allusion had been made to Dobbs's case, and he was glad to have an opportunity of mentioning it, because he thought it was an illustration of the advantage that would have resulted from a preliminary inquiry, inasmuch as if such an inquiry had taken place all the litigation would have been avoided. If a preliminary inquiry were held at an early stage, the inventor would not have to go on blindfolded as he did now; but if he went on after he knew the real state of the case it would be on his own responsibility. With regard to the annual payments, there might be difficulties in the way, but the periodical payments had been very serviceable, and he had no doubt that yearly payments would be found to be the same. He had only one other thing to mention, and that was with respect to the screw-propeller, which, but for the patent laws, never would have been started. The Archimedean Company established it under the operation of the patent laws, and hence its success. With these observations, he would again thank the meeting for the manner in which they had entered into the subject, and he hoped that much good would result from the discussion.

(To be continued.)

THE AMERICAN PATENT COMMISSIONER ON THE POLICY OF PATENTS.

[From the *Engineer*.]

The law requiring the Commissioner of Patents to communicate to Congress an annual report contemplates that, in addition to statistical statements and tables, he should present his reflections upon the working of the laws he is called upon to administer, and exhibit a view of the progress of the arts of the country, which it is his peculiar privilege to observe. The present Commissioner, in his last report, observes:—In discharging this duty I shall take the liberty of departing from the formality of a mere official communication, and address myself, through Congress, by whose munificence the reports of this office are so widely disseminated, to the public, for whose benefit they are mainly intended.

The subjects to which I shall call attention are—the policy of any system of protection by patents; the advantages of our own system as compared with those of other leading industrial nations, and particularly Great Britain; the state of the industrial arts in this country, as exhibited by the inventions examined in this office within the last one or two years; and the modifications of patent laws which, in my judgment, would give greater efficiency to our patent system.

I am aware that, to most inventors in this country, it would seem not less preposterous to question the right of property, or the fundamental laws of morality, than to inquire into the right and policy of granting patents for inventions; but we cannot shut our eyes to the fact that, within the last few years, the policy of patent laws has been the subject of grave discussion in Europe. No later than 1862 a distinguished member of the House of Commons, in England, gave notice of a motion to consider, not the working, but the policy of the patent law itself; and in a debate which arose in May, 1862, upon a motion of Sir Hugh Cairns for an address to the Crown, praying for the appointment of a commission to inquire into the working of the law relating to patents for inventions, members of Parliament stated that, year by year, the opinion had grown more general that, practically, patents did more harm than good to inventors. In 1852 a select committee of the House of Lords was appointed to consider a bill proposed to amend the then existing law of patents. The voluminous evidence taken before this committee has been published, and is full of instruction as to the working of the patent laws in Great Britain, and the questions which arose as to the policy of those laws. The character of the questions which were raised as to the policy of any patent system is exhibited by some of the interrogatories proposed by the committee:—

"Do you think that the fact of a patent being granted is a considerable obstruction to anybody else inventing in that line?"

"You think that in no case where a useful improvement in the course of a manufacture suggests itself to the mind of a man, he would be deterred from making that improvement for fear of being dragged into litigation by reason of his infringing some other patent?"

"Do you not think that the stimulus which a patent gives to a man withdraws a great many ingenious artizans from their usual and more useful work in order to invent things which, when invented, are of no use whatever?"

A question put to Mr. Brunel, an engineer of acknowledged eminence, is, "The result of your evidence is, that you are very decidedly of opinion that the whole patent system should be abolished?"

His answer is: "Yes; I think it would be an immense benefit to that unfortunate class of men whom we call inventors, who are at present ruined and their families ruined, and who I believe are a great injury to society."

"And you think that those consequences, such as ruin to inventors and evils of that description, would subsist equally, though the patent laws were made simple and effective?"

"Yes, I think they would be very much increased; and if patents are continued, I hope the principle will be carried out thoroughly, and then it will not stand for two years."

"I can see every day that the poorer class of inventors ruin themselves by the attempt to work out some idea for the sake of getting a patent, while in all probability, if the man had gone to his master and said, 'Well, it strikes me that by such a means we should be able to get through more work and do something better; what do you think about it?' the chances are that most masters would, if they saw it was a good idea, give the man £1 or a £5 note; and the man the next day would be at work at something else, and you would have out of that man's brains an immensely greater portion of invention, and I believe he would get much better paid for it. I believe he would really make money; whereas now, everybody acquainted with these men knows that they lose money by it, and that an inventor, a schemer, is a poor man, who is more likely to go to the workhouse than anything else."

Mr. J. L. Ricardo, a member of the House of Commons, in his answer to the questions of the committee, forced the free-trade doctrines of his eminent namesake to the utmost verge.

He says: "The result of my experience and observation has been a conviction that the whole system of granting patents at all is very injurious to the community generally, and certainly not of any advantage whatever to the inventor. I consider that it is in a great measure a delusion upon the inventor to suppose that the patent privileges which are granted to him render his invention more valuable than it would be supposing there did not exist any monopoly with regard to it." He regards a monopoly with respect to a particular trade as being in exactly the same situation as a monopoly respecting any particular invention. "The object of a patent is to monopolise a particular trade." He quotes Mr. Say, who considers a patent as a recompense which the Government grants to the inventor at the expense of the consumer. He quotes the opinion of Lord Kenyon, in the case of Hornblower against Bolton, in which he says: "I confess I am not one of those who greatly favour patents; for although in many instances, and particularly in this, the public are greatly favoured by them, yet, on striking the balance on the subject, I think that great oppression is practised on inferior mechanics by those who are more opulent." He does not refer to the views of Lord Mansfield, the great founder of commercial law, who held that "in all work of the mind and of genius the common law of England ought to be held as giving an absolute property." He refers to Lord Bacon, who, in his advice to Sir George Villiers, says: "Especial care must be taken that monopolies, which are the canker of all trading, be not admitted under the specious pretext of public good." But he makes no mention of the tribute to inventive genius which Lord Bacon proposes in his "Atlantis," where he says: "Upon every invention of value we erect a statue to the inventor, and give him a liberal and honourable reward."

The objectors to the policy of a system of protection by patents, as appears by the questions propounded by the committee of the House of Lords, and the answers above quoted, may be resolved into three classes:—

1. Those who honestly doubt whether the system of patents affects the assumed development of the industrial resources of the nation; 2. Those who believe that the progress of a nation is to be secured only through the encouragement and instrumentality of the favoured classes; and 3. Those who, carrying the abstract principles of free-trade to too great a generalisation, deny the policy of any law which savours of a monopoly, or effects even a temporary protection of industry or genius. The objections of the first class I will hereafter attempt to answer in detail. Those of the second class, not openly favoured under the present political condition of affairs in this country, have found sympathy with a class now—happily, perhaps—removed from us, who always regarded with contempt the poor inventors of the North. It is this spirit which breathes in the language of the eminent engineer, who conceives that the poor inventor would be sufficiently rewarded by receiving a £1 or a £5 note from his master. It is unnecessary to reply seriously to this class of objectors. They can be found only in a country where the avowed objects of the laws which regulate the descent of property are the concentration of wealth in the hands of the few, and the support of hereditary aristocracy; where the husbandmen on small properties have been driven from the land, in order that 2,000 proprietors may possess among them one-third of the land, and the total revenue of the three kingdoms; where the doctrines of political economy prevail that large farms, large machine shops, large cotton mills, and large ironworks can produce cheaper than small ones, and therefore very properly supersede and obliterate them; and where a theologian no less respected than Dr. Chalmers can be found to affirm the blessings of a splendid aristocracy, "that from this higher galaxy of rank and fortune there are droppings, as it were, of a bland and benign influence on the general platform of humanity."

There is, unfortunately, in this country, more sympathy with the last class of objectors, who regard, with Mr. Ricardo, a patent obnoxious, as a remnant of the old abuse of monopolies, by which an individual obtained from the Crown the exclusive right to exercise some particular trade, and who consider the patent laws as a product of the semi-barbarous age of Queen Elizabeth. During her reign the sole right to buy and provide steel within her realm was granted to a single nobleman. The sale of salt, starch, leather, paper, &c., was restricted to favoured persons, who, in some cases, raised the prices to 1,000 per cent. and upwards. It was this class of monopolies against which Lord Bacon inveighed. The evils of this policy increased to such an extent, that it was considered by the Parliament of James I. altogether incompatible with the prosperity of the country. This feeling produced, in the 21st of James I., the famous "statute of monopolies"—famous not only for the abolition of the former unjust monopolies of trade, but for establishing the rights of inventors, which date, according to Blackstone and other English jurists, from that law. The statute suppresses monopolies by making void the future grants of all such as do not come under the following proviso:—"Provided also, and be it enacted, that any declaration before mentioned shall not extend to any letters patent and grants of privileges for the term of fourteen years or under, hereafter to be made, of the sole working or making of any manner of new manufacture within the realm, to the true and first inventor or inventors of such manufacture, which others at the time of making such letters patent shall not use, so as also they be not contrary to law, nor mischievous to the state, by raising the prices of commodities at home, or hurtful of trade, or generally inconvenient." Certain patents, more of the character of the old monopolies of trading, which paid a yearly rent to the exchequer, were exempted from the operation of the statute. The date of the act was 1624. In 1639, great discontent having arisen in the public mind with respect to the monopolies and privileges which remained, there was issued a proclamation abolishing a great many of the privileges which still existed, and, among others, "all patents for new inventions not put in practice from the date of their respective grants." There was thus in the general statute abolishing monopolies, and the subsequent proclamation clearing away such as subsisted, a distinct recognition of the claims of useful inventions to exemption.

It is a curious fact in the general history of the origin of the patent policy, that the original object in granting patent privileges in France, as stated by M. Wolowski, professor of commercial legislation, in the evidence before the committee of the House of Lords, was to break up the monopoly of the guilds of trade, which formerly existed in France, as well as in almost every city in Europe. All the persons practising any one art or trade in a particular city, such as the tailors, the brewers, the tanners, the goldsmiths, &c., were united into a company, which received from the government the exclusive right to practise their vocation. The competition of the art or trade was thus restricted to those who had been made free of the company; and no person could be made free until he had complied with regulations, often intentionally made numerous and vexatious, in order to prevent too many persons entering the business. No member of the guild could work, except in conformity with its rules. An inventor of any improvement in the trades practised by the guild, not a member thereof, could not employ his own invention; a patent gave the inventor the right of working individually, in derogation of the chartered monopoly of the guild. According to M. Wolowski, patents are now granted in Austria for the same object. Thus, the dawn of the rights of inventors has been actually coeval with the destruction of monopolies, odious to the common justice of men. And the common sense of mankind has marked a distinction between such monopolies and the exclusive rights conceded to inventors. Their rights under patents are called monopolies only from the poverty of language, which has failed to express in words a distinction which no less clearly exists. The odious monopolies, or those properly so-called, such as were given in the time of Elizabeth, for the sale of salt, starch, paper, steel, &c., were grants simply to aid individuals in amassing wealth, and favoured the aggregation of property in a few hands without opening new sources of national wealth, and were thus in derogation of the rights of others without compensatory public benefit, and were, therefore, positively injurious. Prof. Bowen has shown, in opposition to the dogmas of Adam Smith, that individual and national wealth are not identical; that individuals grow rich by the acquisition of wealth previously existing; nations, by the creation of wealth that did not previously exist. "Invention," says Mr. Ray, according to Prof. Bowen, "is the only power on earth that can be said to create. It enters as an essential element into the process of the increase of national wealth, because that process is a creation, and not an acquisition. It does not necessarily enter into the process of the increase of individual wealth, because that may be simply an acquisition, not a creation." "Hence," continues Mr. Bowen, "the most frequent cause of the increase of national wealth is the increase of the skill, dexterity, and judgment, and of the mechanical contrivances, with which national labour is applied." In this view, how can a monopoly of a trade be compared with the exclusive right in an invention? How can the exclusive privilege to sell salt in Elizabeth's time, which added not one bushel to the production, but which enriched the monopolist and robbed the community, as was the fact, by raising the price from sixteen pence a bushel to fifteen shillings, and the exclusive right of Whitney to his invention of the cotton gin, which has added hundreds of millions to the products and exports of the country, be both branded, with equal justice, with the odious name of monopoly?

The argument of the distinguished member of Parliament, Mr. Ricardo, against patents, on the ground of their being monopolies, may have less weight when the immediate practical grounds of his objections are considered. It appears from his evidence before the committee that he was chairman of the Electric Telegraph Company—the great company which, under Messrs. Cooke & Wheatstone's patents, and a charter from Parliament, exclusively controlled the system of telegraphic communication in England.

It appears that the company paid for the patent rights under Messrs. Cooke & Wheatstone, the sum of £140,000, and that the company had paid

nearly £200,000 in buying patents, and litigating them; that the company had bought up a very large number of patents which interfered with their exclusive rights, because they had made it a rule, if a man offered reasonable terms, to buy an invention, however bad it might be, sooner than litigate it; and that they paid for one patent—that of Mr. Bains—£8,000 or £9,000, which, although it did not quite come up to the expectation of the company, they found useful in combination with other patents. The obvious question occurs how, but for the existence of the patent laws which recognised the rights of the company to the exclusive use of Messrs. Cooke & Wheatstone's and Mr. Bains' patent, for which they had paid the inventor a full equivalent, could they have had the means of reimbursing themselves for the vast expenditure for the original and competing patents? What more instructive illustration could be found, except the whole free-trade policy of Great Britain, of the fallacy of political economy founded simply upon the individual interests of men and nations?

It is gratifying to observe that Mr. J. S. Mill, admitted to be the ablest living writer upon political economy, and a strong advocate of free trade, thus frankly admits the reasonableness of granting patent rights:—"The condemnation of monopolies," he says, "ought not to extend to patents, by which the originator of a new process is permitted to enjoy, for a limited period, the exclusive privilege of using his own improvement. This is not making the commodity dearer for his benefit, but merely postponing a part of the increased cheapness which the public owe to the inventor, in order to compensate and reward him for the service. That he ought to be both compensated and rewarded for it, will not be denied; and also, that if all were at once allowed to avail themselves of his ingenuity, without having shared the labours or the expenses which he had to incur in bringing his idea into a practical shape, either such expenses and labours would be undergone by nobody, except by very opulent and very public-spirited persons, or the State must put a value on the service rendered by the inventor, and make him a public grant. This has been done in some instances (as when Parliament offered a reward of £20,000 for a method of finding a ship's longitude at sea), and may be done without inconvenience, in cases of very conspicuous public benefit; but, in general, an exclusive privilege of temporary duration is preferable, because it leaves nothing to any one's discretion; because the reward conferred by it depends upon the inventions being found useful, and the greater the usefulness the greater the reward; and because it is paid by the very persons to whom the service is rendered, the consumers of the commodity."—*Political Economy*, vol. ii., p. 497.

CORRESPONDENCE.

TELEGRAPH COMMUNICATION ON RAILWAYS.

To the Editor of the Telegraphic Journal.

Sir,—Will you kindly give publicity to the following. It will, I have no doubt, lead to a little reformation. On Tuesday last I was a passenger by the 10.44 up train from Putney in the evening; there were a great many passengers who had been waiting about three-quarters of an hour for two trains that were then overdue. Owing to some derangement, the 10.44 train did not arrive until 11.25, making three trains overdue. The station-master could give no reason for the delay, nor could he say when a train would arrive. In answer to my inquiry as to whether there was telegraph communication, he informed me there was, but that it was a distinct company altogether from the railway; the telegraph company's clerk had long since left, and there was no one else that understood the working of it.

How far this system may be carried out on other railways, I cannot say, but it is evident that such bad arrangement must cause great inconvenience to the public, and diminish to a certain extent the safe working of the line. If any accident or cause of delay arises, the station-master has no means, after the telegraph company's clerk has left, of being informed unless by special train. I think it but right that, as long as a railway station remains open for traffic, there should be some one upon the premises capable of working the telegraph. The station-master informed me that it was not required of him as a qualification, and he knew nothing about it. The London and South-Western Railway is, I believe, as a rule, a very well-managed line, and the company will, I have no doubt, see the necessity of remedying a defect that may be done at, comparatively speaking, so little cost, and will enhance the security and convenience of its passengers to a very great extent.—I am, sir, yours, &c.,

A Railway Passenger.

Patents.—A Berlin paper has the subjoined:—"The Minister of Commerce last year instituted an enquiry to ascertain whether the issue of patents for inventions had not become useless, owing to the progress of industry, and requested the forty-seven Chambers of Commerce, in Prussia, to give an opinion on the subject. Thirty-one of them have now replied that the abolition of patents would be advantageous in an industrial point of view, while the other sixteen express the opposite opinion. When the same question was submitted to the Chamber of Commerce, in 1853, only six were for suppressing patents."

PARLIAMENTARY NEWS.

THE RUSSO-AMERICAN TELEGRAPH.

Mr. Watkin asked the Secretary of State for the Colonies if any application had been made to her Majesty's Government, or to the local authorities, by or on behalf of Mr. Collins, the concessionnaire of the Russo-American line of telegraph, intended to pass viâ Behring's Straits, for permission to carry a portion of such line through British Columbia; and if so, whether such permission had been or was proposed to be given.

Mr. Cardwell said that such an application had been made to the Colonial-office, but it was not only an application to pass through British Columbia, but it was an application for an exclusive privilege. The answer returned granted the right of passage, but disapproving of that part of the application relating to exclusive privileges.

TELEGRAPHIC COMMUNICATION WITH THE PACIFIC, AND GOVERNMENT CONTROL OVER THE HUDSON'S BAY TERRITORY.

Mr. Crawford asked the Secretary of State for the Colonies whether any progress had been made in the negotiations between her Majesty's Government and the Hudson's Bay Company relative to the establishment of telegraphic communication with the Pacific through British North America, and whether arrangements for the future management of the territory of the Hudson's Bay Company were still the subject of negotiation.

Mr. A. Mills asked the Secretary of State for the Colonies whether her Majesty's Government exercised at the present moment any control over the territory claimed by the Hudson's Bay Company, and stated in their prospectus, issued in July last, to comprise 1,400,000 square miles; and whether it was in contemplation to establish a Crown colony in any portion of this territory.

Mr. Cardwell said no authority was exercised over the territory in question, except by the Hudson's Bay Company. Negotiations had been for some time in progress between her Majesty's Government and the Hudson's Bay Company, having for their object the transfer of a large portion of that territory to the Government of the Crown, in order to found a colony in Rupert's Land, and to establish telegraphic communication with the Pacific. These negotiations had been going on since last session, but as yet no answer had been received.

LAW INTELLIGENCE.

Newall *v.* Elliot and others.—This was an action for the infringement of a patent for laying down submarine electric telegraph cables. The trial, which took place before the Lord Chief Baron at the sittings in Middlesex after last Hilary Term, occupied five days, and resulted in a verdict for the plaintiff on all the issues, with 40s. damages. The alleged infringement was in the laying down of the cable from Rangoon to Singapore in November, 1860. The case now came before the Court of Exchequer upon a rule to enter the verdict for the defendant, or for a new trial.—Mr. Grove, Q.C., the Hon. George Denman, Q.C., Mr. Serjeant Ballantine, Mr. Quain, and Mr. Markby were counsel for the plaintiff; and Mr. M. Chambers, Q.C., Mr. Cleasby, Q.C., and Mr. Bidder for the defendants.—The arguments of counsel have occupied the greater part of four days.—The Lord Chief Baron said that the object of the rule was, first, to enter a verdict for the defendants upon the question of the infringement of the patent; and next, for a new trial on the ground that the verdict of the jury was, if not altogether unsupported by the evidence, undoubtedly contrary to the weight of evidence; and thirdly, a question was raised with respect to the validity of the patent itself. With regard to the first point they were all of opinion—his brother Martin entertained some doubt upon the question, but not sufficient to differ from the rest of the court—that the verdict ought to be entered for the defendants on the infringement. They considered there was no evidence to go to the jury of any infringement, in point of fact, either in this country or elsewhere. With respect to the second point, the court had nothing but a choice of difficulties—viz., to give the defendants the benefit of a new trial on the ground of the verdict being against the weight of evidence, or to deprive him of that, and allow the Court of Error to say whether there was any evidence at all, and if there was, the verdict for the plaintiff would remain. As the counsel for the plaintiff had refused to consent to any arrangement, which would have prevented that, he did not see how the court could do justice between the parties without following the precedent originally adopted by this court, and followed by the Courts of Queen's Bench and Common Pleas, and suspending the question of a new trial until the judgment of the Exchequer Chamber, or perhaps, the House of Lords, on the point of law, had been obtained. The result of the judgment of the court would be, that the rule should be made absolute to enter the verdict for the defendants on the point of infringement, that the question of a new trial should be reserved, and that the rule should be discharged with respect to all the other matters.—Mr. Baron Martin said that while concurring in the judgment of the rest of the court, if the decision of the case had

depended entirely on his opinion he would have made the rule absolute for a new trial, although he personally did not entertain much doubt that there was no evidence of an infringement to go to the jury.—Mr. Baron Bramwell was of opinion that the verdict should be entered for the defendants on the issue of not guilty, there being no evidence of any infringement of the patent.—Mr. Baron Channell expressed the same opinion.—Rule absolute accordingly to enter a verdict for the defendants on the plea of not guilty.

TELEGRAPHIC NEWS.

BRISBANE, QUEENSLAND.—The northern telegraph extension in this colony is being rapidly proceeded with.

THE MAGNETIC TELEGRAPH COMPANY.—The wires of the above Company on the Dublin and Wexford Railway have been completed as far as the new bridge at Avoca.

THE BONELLI TELEGRAPH COMPANY.—The allotment of shares in the above company took place on the 30th ult. We understand that the company intend to proceed at once to construct their lines between London, Liverpool, Glasgow, Manchester, &c., and ultimately to Ireland.

INSTITUTION OF CIVIL ENGINEERS.—At the President's meeting on the evening of the 30th ult. various telegraphic instruments were exhibited, including those of Messrs. Siemens, Halske, & Co., the Bonelli Telegraph Company, W. T. Henley, Reid Brothers, Silver's India-rubber Works and Telegraph Cable Company.

QUEENSLAND.—The commercial relations of this colony with other countries is unmistakeably evidenced by the large amount annually derived from its various means of communication. From the census recently published, we find that the receipts of the post office last year were £11,481, while the income of the electric telegraph department amounted to £4,120.

NEW SOUTH WALES.—The railway traffic and telegraph business of our colonial possessions are rapidly increasing, and steps are being taken to further develop these two important systems in every direction. In New South Wales the increase in the receipts of the year 1863 over 1862, were, on railways, £33,747 18s., on telegraph messages, £8,464 7s.

ALARMING ACCIDENT IN THE VICINITY OF A TELEGRAPH STATION.—The following telegram was received by Messrs. Glass, Elliot, & Co., viâ Malta and Alexandria telegraph, from their superintendent at Malta, dated May 30th, 4.35 P.M.:—"Powder magazine exploded near Tripoli station. Forty men killed. Telegraph station much damaged. Clerks safe. Line joined through to Benghasi. Traffic with Alexandria not interfered with."

ANOTHER ATLANTIC TELEGRAPH COMPANY.—By a bill which has just passed the Corps Legislatif in France, the convention entered into between the French Government and Messrs. Bowett, Simon, and Trotter for the establishment of a submarine line of telegraph between France and the United States, either direct or viâ the island of St. Pierre and Mequdon (Newfoundland) or the Azores, has been ratified.

ORAN AND CARTHAGENA CABLE.—We had, a few weeks ago, to announce to our readers a mishap in the effort to submerge the above cable. A sufficient length has now been manufactured at the works of the Telegraph Construction and Maintenance Company, Wharf-road, City-road, and East Greenwich, to replace the portion which was lost in the first attempt to submerge it. The depth of water between Oran and Carthagena is, on an average, 2,400 fathoms.

THE ELECTRIC AND INTERNATIONAL DRAMATIC CLUB.—The members of the above popular club gave their fifth entertainment at the Cabinet Theatre, Liverpool-street, King's Cross, on the 26th ult. The theatre was exceedingly well filled by the friends of the society. The following proved a very effective caste for the Messrs. Morton's comic drama, "All that glitters is not Gold":—Sir Arthur Lassell (Mr. Gerrard); Jasper Plum (Mr. Perry); Stephen Plum (Mr. James Cook); Frederick Plum (Mr. Tripe); Toby Twinkle (Mr. Coleman); Harris (Mr. Simmons); Lady Leatherbridge (Mrs. Malcolm); Lady Valeria Westendleigh (Miss Helen Gower); Martha Gibbs (Miss Agnes Burdett). The company fully appreciated the excellence of the performance, if we may judge from the hearty applause which it evoked. We were, like every one else present, much delighted with the acting of Mrs. Malcolm, the Misses Helen Gower, and Agnes Burdett, and with that of the "*Plums*," who certainly "*were not*," as insinuated, "*blighted*." Mr. Coleman, the "Galvanic Battery" of the evening, maintained a steady *current* of hilarity, and certainly kept the audience from re-Morse. In the intervals of the performance Mr. W. Eaton executed several fantasias on the pianoforte in a very creditable manner, and was deservingly applauded. The proceedings of the evening were brought to a conclusion by a representation of Mr. Fitsball's domestic drama, "The Momentous Question," in which the following amateurs took part:—Robert Shelly (Mr. Perry); James Greenfield (Mr. Garrard); Union Jack (Mr. Coleman); Chalk (Mr. Simmons); Moletrap (Mr. Hodges); Bachel Ryland (Miss Helen Gower); Fanny Dossett (Mrs. Malcolm). During the performance of this piece we were provoked to remonstrate with a few persons in the reserved seats for their persistent rude behaviour. If they are in any way connected with telegraph companies, this may come under their notice, and it is to be hoped that on a future occasion we shall be spared the painful duty of referring to their misconduct with greater severity.

THE PROGRESS OF TELEGRAPHY.—We are very anxious to be in possession of every information respecting the extension of telegraph lines both for public and private purposes. To our numerous subscribers abroad the information cannot but be interesting, as the progress of the science in distant lands is interesting to ourselves. To our foreign correspondents for the valuable information contributed from time to time to our columns, we return our most sincere thanks, and trust that we shall be honoured by the continuance of such favours. The progress of private telegraphy within the last few months at home has been most satisfactory. Private firms at Coventry and Derby have availed themselves of the great advantages which a ready, simple, and instantaneous means of communication afford them between their distant establishments. These works were executed, as we are informed, by Messrs. Reid Brothers, of the Wharf-road, City-road, London. The same firm has also just completed a line of telegraphy on the Portland and Weymouth Railway, and another between the city offices of Messrs. Corrie & Co. and their coal wharves at Purfleet, Essex.

FLOATING TELEGRAPH STATIONS.—Some years since Prince Albert, who was then an Elder Brother of the Trinity House, suggested that the light ships round our coasts should be connected with the shore by means of electric cables. The question was considered, but no means had then been considered by which a ship swinging at her moorings could be permanently connected with her cable, and the far-sighted proposal was not carried out. A company now forming proposes to do that which Prince Albert suggested should be done, their object being in the first place profit, but incidentally carrying out the Prince's philanthropic ideas. The first ships to which this novel extension of the present network of telegraphs will be applied are to be stationed off Scilly and Cape Race, and at both stations it is allowed that not only will a large telegraphic business be transacted, but that many salvage services will be performed beneficial to distressed ships' crews, and resulting in profit to the salvors for the services rendered.

THE PERSIAN GULF TELEGRAPH.—Advices just received through Bagdad and Beyrout describe the causes of delay in the transmission of intelligence through the telegraph to India, the submarine portion of which in the Persian Gulf was recently completed by Lieutenant-Colonel Stewart and Sir Charles Bright. It appears that 170 miles of the line from Bussorah to Bagdad are incomplete, and cannot be constructed on account of the disturbed state of the intervening country, the Arabs having revolted against their Turkish masters. The Porte undertook to construct this portion of the telegraph through the Pashalic of Bagdad; but in consequence of hostility from the Arabs, not a Turk, it is said, dare venture into the district unless protected by a military force. These Arabs, however, it is affirmed, would permit the English to carry on the work; yet so jealous are the Sultan's Government of our doing anything within his territory, that they would rather have this great undertaking indefinitely obstructed than permit us to act. The consequence is, that messages must be conveyed over the incomplete portion on horseback, which causes a delay of about six days. It appears also that this is not the only present cause of interruption, a break having occurred in the route from Bagdad to Constantinople, one stage from Bagdad, "where the line is so wretchedly looked after, and the Turks are so slow about repairs, that it is impossible to say when it will be again in working order." The details thus given furnish a literal confirmation to all that was predicted seven years ago when the English Government, after having encouraged the Euphrates Telegraph Company, which had been formed by Mr. Andrew, to incur a considerable outlay, suddenly abandoned the enterprise in order that the Turks themselves might carry it out, and that our own resources might be expended on the Red Sea line, where a million of British capital has been hopelessly sunk. [We shall refer to this important subject on a future occasion, especially with reference to the extraordinary claim urged on behalf of Mr. W. P. Andrew.—ED.]

MISCELLANEA.

PUCK AND THE ELECTRIC TELEGRAPH.—Writers on telegraphy have been in the habit of quoting the famous and prophetic words put in the mouth of Puck by our immortal bard, as to the ultimate triumph of the electric telegraph. In *Notes and Queries* of the 14th ult., a correspondent has contributed the following interesting information:—"In a collection of Fairy Stories and Folk Lore I made in India from verbal relation, there is mention of a fairy called Gŭrŭ Pŭck, said to have the head of a bird, with wings springing from his shoulders, indicative of his rapidity of movement. He is unquestionably the original of the Puck of Shakespeare, whose chief attribute, as manifested in the following lines, was celerity of locomotion:—

> "*Puck.* 'I'll put a girdle round about the earth
> In forty minutes.'

"Shakespeare's Puck, like the Indian fairy, sometimes wears the head of an animal:—

> "*Puck.* 'Sometimes a horse I'll be; sometimes a hound,
> A hog, a headless bear; sometimes a fire.'

Gŭrŭ Pŭck is the messenger of the higher powers; his eyes are lightning, and rays of fire issue from his body, in which respects Puck, the English fairy, also resembles him. H. C."

Novel Application of the Electric Light.—The *Echo* of Honfleur states that for some time past a person from Paris, with an official introduction, has been prosecuting a series of experiments with electric light in fishing. The fish attracted by this great light arrive in shoals at the surface of the water, and are easily taken with an ordinary net.

Waste Electricity to be used up.—At the last sitting of the Paris Academy of Sciences, a paper by M. Loir was sent by the Minister of the Interior, in which the author endeavoured to show that a quantity of electricity was produced in large factories, and might be turned to profitable account by means of the straps which generated it by their friction in communicating motion to the machinery.

Vested Interests v. The Public Weal.—The Pneumatic Despatch Company proposed to carry their tunnel through Holborn and Skinner-street to the General Post Office from Euston-square, and with that view they asked permission of the authorities of Christ's Hospital to carry it below the precincts of the hospital to avoid the great public inconvenience which would be caused by excavating through Newgate-street. The result has been that the governors of the hospital have entirely refused to allow any such work to be undertaken within their property. The Pneumatic Despatch Company have a Bill now passing through Parliament, by which they proposed to obtain compulsory power to effect their object of passing through the hospital, but they have met with such strong and decided opposition from the governors that they have withdrawn from the Bill the clauses which were meant to confer such compulsory powers.

Mr. Varley on the Atlantic Telegraph, at the Inauguration Banquet given by Mr. C. W. Field.—It is my opinion that you should get rid of the Government guarantee, which is of no benefit if the cable works, and none whatever should it unfortunately fail. It, however, fixes the maximum charge that can be made to the public, beyond which you cannot go, and this amount is, in my opinion, far too low, when it is considered that your cable will have to connect the whole of the vast telegraphic system in the United States, in Canada, in Nova Scotia, with the innumerable telegraphic ramifications of Great Britain, the continents of Europe, Africa, and Asia. At present there are between thirty and forty wires connecting England with Europe, and these are for the most part full of traffic. If, then, so many wires be required for the business between England and the rest of Europe, how many will be required to connect the one half of the world to the other—certainly more than one cable. If, then, your rates be so low that you have more work than your wire will transmit, great delay will be the consequence, and I am perfectly certain that, unless you charge very much more than the maximum fixed by the Government, your cable will be so deluged with work, that your telegraph will be slower than the mail packet. The only remedy for this is to charge so much money that the number of messages received within the twenty-four hours shall be sufficiently limited to be transmitted within that time, otherwise you would get more and more behind every day. A telegraph is of no use unless it does its work with certainty and despatch. If you take the steps I recommend, the commercial success of the undertaking is guaranteed. Your earnings will be vastly greater than what you have hitherto calculated. Why, the telegraph from New York to California has paid cent. per cent. per annum. If one wire be barely sufficient to transact the business between California and the rest of the United States, how is it possible that one wire shall be sufficient between Europe and America? I feel great confidence that when once a cable is successfully laid across the Atlantic, the demands upon it will be so great, that you will have to lay one or two per annum for the next twenty years, or even more. With regard to the science of the question. I claim to be a practical, as well as a theoretical man, and in order to study the best means of utilising your cable when laid, it occurred to me that the best method of proceeding was to construct an artificial Atlantic cable, possessing the same electrical conditions, and consequent retardation as that which the cable about to be manufactured will have. This I have succeeded in doing, and I have already tried a number of experiments in it. There is no doubt that through an Atlantic cable 1,900 miles in length, and of the dimensions of that now about to be made, eight words per minute can be transmitted, and I have considerable hope that we shall be able to increase that number to twelve or thirteen. Judging from the rates charged, and willingly paid, for messages between California and New York, and also between Alexandria and London, I feel no doubt whatever that if you charge so much per message as shall only just keep your cable from being blocked up with work, it will pay 200 or 300 per cent.

PATENTS.

APPLICATIONS FOR LETTERS PATENT.

1298. W. Passmore, making light machines or apparatus (such as sewing machines, rotary hair-brushing machines, model machinery, electrical apparatus, small lathe or other machinery or apparatus to which band, line, or cog is applicable) self acting.

1303. G. Schaub, an improved mode of transmitting currents of electricity for telegraphic purposes.

NOTICES TO PROCEED.

241. N. J. Holmes, improvements as applied to the regulation of machinery for covering telegraph cables, wires, and other similar articles.

241. G. Canouil, an improved alarum and signalling apparatus.

PATENTS SEALED.

3012. J. G. Redman and G. Martin, improvements in compounds or compositions for coating or covering iron or wooden ships and vessels, metallic sheathing, telegraphic cables, and other objects, to preserve them from decay, fouling, or other destructive action.

3031. J. Harper, improvements in apparatus for straining wire.

PATENTS WHICH HAVE BECOME VOID.

1166. J. R. Hunt, improvements in the manufacture of gutta-percha and compounds thereof with other matters and substances.

1246. F. N. Gisborne, improvements in the construction of electric targets for rifle and gun practice.

PATENTS ON WHICH THE STAMP DUTY OF FIFTY POUNDS HAS BEEN PAID, AND DATES OF THEIR PRODUCTION FOR CERTIFICATE.

1378. F. N. Gisborne, improvements in the means of and apparatus for indicating the course to be steered in ships at sea, and in galvanic batteries to be used in some cases therewith.—Dated 1st June, 1861.

1329. C. S. Duncan, improvements in the construction of electric telegraph cables or ropes.—Dated 27th May, 1864.

PATENTS ON WHICH THE STAMP DUTY OF ONE HUNDRED POUNDS HAS BEEN PAID, AND DATES OF THEIR PRODUCTION FOR CERTIFICATE.

1665. A. V. Newton, an improvement in the manufacture of sulphuric acid.—A communication.—Dated 13th June, 1857.

THE PERSIAN GULF TELEGRAPH.

THE importance of the work in which Col. Stewart and Sir Charles Bright are now engaged increases daily, and their every movement is watched with the greatest interest at home and abroad. It is impossible to over-estimate the advantages which will result from the establishment of telegraphic communication with our Indian possessions, and we anticipate the success of this great undertaking as one calculated to inspire the friends of submarine telegraphy with greater confidence in other similar projects now in course of realization. In a previous number of this journal we laid before our readers a report, from the *Times of India*, of the progress made in the submersion of the Persian Gulf Telegraph cable, but as the account before-mentioned lacked many important details, we have endeavoured to procure accurate information, and have been favoured by Mr. Latimer Clark, the engineer of the Indian Government, with interesting particulars furnished by the correspondence of gentlemen engaged in the various operations in the Gulf. Mr. Latimer Clark writes :—

To the Editor of the TELEGRAPHIC JOURNAL.

SIR,—The following extracts from letters received from the gentlemen engaged in the Persian Gulf Telegraph expedition, may probably interest your readers.—I am, sir, your obedient servant,

June 8th, 1864. LATIMER CLARK.

April 26th. "We put four miles on board the Comet, and sent her round to Fao. The cable was used to get overland to the water's edge, but it was a long job carrying it in pieces, as you may imagine; about a mile was laid by boats, in a sort of canal running inland from the Shat-el-Arab side, but the rest had to be carried on men's backs. On the 4th, after the arrival of the Amberwitch (it blew too hard on the 3rd to do anything), we coiled five miles of cable into the Zenobia's two paddle-box boats, and the Coromandel's two barges, and at 10.30 A.M. on the 5th, started for shore, having buoyed the end of the cable a short distance from the Assaye. We went in as close as the Amberwitch's draught (12 feet) would allow, about four and a-half miles from the water's edge, and laid out the cable from her in the boats as far as we could. We stuck, however, about three-quarters of a mile from the water's edge, and as the tide was just on the turn (we had taken near high-water time for landing, and thus had about an hour of slack water to get in) we were soon high, but not dry, in the mud. How we got the cable from the boats to the end of the cable taken over the land, would make a good picture for *Punch*. The mud was so soft that it was impossible to walk, in fact we were up to our middles directly we got out of the boats, so we had to crawl through it on all fours like turtles, and you may imagine the figures we all presented, clothes, face, and hair, all over mud. However, we did the job, and got on board the Coromandel (which had gone round to the Shat-el-Arab, or Fao side, with Col. Stewart) for the night.

"The cable has behaved remarkably well throughout; we have had no sticking, not a single broken wire (against which the outer covering is a capital guard), and the testing has been wonderfully uniform throughout. The most perfect goodwill exists throughout the whole fleet, from the senior officer down to the cabin-boys, and likewise amongst our own staff, and it is quite a pleasure to work under such circumstances. I should tell you that the line works admirably, that the messages go through excellently, and the whole system between Kurrachee and Fao is in perfect order; the land line from Gwadur to Kurrachee also works capitally; but between Kurrachee and Bombay the working is infamous and most irregular. Sometimes when the latter is working well we get a message from Bombay in half-an-hour, sometimes they are stopped for a whole day, and once for two days; good working is quite the exception. The Persian line, I am glad to say, offers promise of being finished soon, and as the Russians have now got into communication with Persia, by a line now at work passing through Tabreez to Teheran, it is not unlikely that after all, that route (meeting the cable at Bushire) will be the first open. Captain Champain, and several other R.E. officers and men are hard at work in different sections of the Bagdad, Ispahan, Shiraz, and Bushire line, and it is thought they will finish in July. The difficulty between Bagdad and the cable end at Fao or Bushire is but temporary, and may perhaps be turned to account at Constantinople in getting further concessions as to having European clerks, &c.; for here is another great difficulty between this and Constantinople at present, *all messages are translated from English to Turkish here, and back again at Constantinople.* Fancy a commercial message written at Bombay and the result as presented to the wondering merchant in London! This is, however, to some extent provided for in a convention just arranged in Constantinople, in which it is provided that the officials appointed shall be acquainted with the English language.

May 9th. "The Amberwitch went on ahead, and took up positions arranged at the most critical points, burning blue lights at night, and having a blue ensign at mast-head (when in position) by day. All went very well until 7 P.M. on the 4th, when we were struck by a tremendous squall, with rain, lightning, and clouds of fine sand. The sand was so dense that we could see nothing of the lights of the Zenobia, although she was of course close to us, as she has us in tow. The wind was very strong, and, getting under the awnings before we could furl them, acted like a mizen, and made the ship broach to in spite of her helm being hard up and the fore topmast staysail set, the only head sail we dared set for fear of its carrying away. The awning blew up into an immense arch, and then went off like a gun, breaking the heavy iron stanchions like carrots, and carrying them into the air, and then dashing them down on the deck, burying the break and machinery in the wreck. Fortunately nobody was hurt, although we had just called the watch below to furl awnings, and the quarter-deck was crowded with men. We cleared the wreck away as fast as possible, and most fortunately nothing got into the wheels, although the ridge chain of the awning took up a position on the top of the break-drum, which was going at 45 revolutions per minute, or 8½ knots an hour, although the Zonobia's engines were stopped. I think you will allow that this rate says something for our paying-out arrangements. The dust or sand was wonderful. We were all like millers with grey beards and hair, and could hardly see out of our eyes. Fortunately the wind died away before we came to the end of the cable, which we did at about 11 P.M. We buoyed the cable all night with two buoys and a flag buoy, and then ran for Ormarra. We got in there on the 5th at daylight. The ship looked like an Arctic ship in the winter. She was white from truck to gunwale, and about an inch of sand all over her decks. I got the Amberwitch astern of us same day, and took out all odds and ends from Assaye, and pulled machinery to pieces.

6th. "Waiting for Cospatrick; made arrangements with naval men for further operations on the rest of section.

7th. "Cospatrick arrived, commenced getting stores, &c., over.

8th, Sunday. "Rested, as we had not had a Sunday for some time, and everybody was fagged.

9th. "Came out (by arrangement) to anchor near buoys and pick them up at daylight.

"The Cospatrick to come out to-morrow at daylight. Have found buoys, but buoy on end is gone, and flag buoy has drifted. Buoy on bight all right. Shows the prudence of two buoys.

April 29th. "I write to inform you that the whole of the cables laid in the Persian Gulf work and test satisfactorily, the resistances being as follows :—

"GWADUR—MUSSENDOM SECTION.

March 16th. "Resistance of gutta-percha, 358 mills. per knot.
" copper, 6·7 units "

"This cable landed at Mussendom February 13th, the resistances then being—

"Gutta-percha, 339 mills. per knot.
Copper, 6·72 units ,,

"Mussendom—Bushire Section.

"This cable landed at Bushire March 24th.
March 25th. "Resistance of gutta-percha, 361 mills. per knot.
,, copper, 6·4 units ,,

"Bushire and Fao Section.

"Assaye anchored off Fao March 27th.
March 27th. "Gutta-percha resistance, 630 mills. per knot.
Copper ,, 6·68 units ,,

"There are three reasons why this section should test better than the other two: first, the cable is composed of the coils bearing low numbers, and first supplied by the Gutta-Percha Company—the coils, if you remember, had a very much greater resistance when tested at the Gutta-Percha Works than those supplied at a later date; the second reason, the greater age of the manufactured material; thirdly, the lower temperature of the water the cable is submerged in, the temperature being at the depth of 29 fathoms in Malcolm's Inlet 22°, and only 17° in 24 fathoms about 70 miles from Fao. From soundings at different parts of the Gulf, I find the temperature decreases slightly between Mussendom and Bushire, and very quickly between Bushire and Fao. The day after we anchored at Fao we were suddenly surprised by a loss of continuity in that section, while the insulation remained perfect. The distance by test showed it to be 93·33 miles from end of cable at Fao. This distance was determined by charge and discharge test, with the use of the condenser. After repairing the cable, and reducing the distance to a mile mark, picked up in cutting out the fault, the distance of the fault was found to have been from end of cable on board Assaye at Fao 93·4 miles. The cable broke on Monday at noon. Cable to the amount of twenty miles was put on board the Amberwitch. Test made from the Bushire end of line. Cable repaired, and Amberwitch back again at Fao by daylight the following Sunday, so that the landing of the cable at Fao was not delayed by this our first mishap at all.

"We have fortunately had beautiful weather for laying these three sections, and therefore tests are all that can be wished for. If the ship is rolling it is impossible to test the copper resistance, owing to a magneto-electric current being generated in the cable by the earth's magnetism; coming down to Gwadur these currents have been sufficiently strong to deflect Thomson's mirror galvanometer 140 divisions on each side when the ship was rolling 10° on each side, the sensibility of the instrument being with one cell, through 10,000 units, 1·45 divisions."

M. HIPP'S ELECTRIC SAFETY DISTANCE SIGNAL FOR RAILWAYS.

M. Hipp is an electrician of Neufchâtel, and the signal is patented as a communication to Mr. John Imray, engineer, London. The idea involved in its construction is extremely ingenious, but it would be hopeless to attempt to explain the mechanism without engravings. Suffice it to say that the signal consists of a column surmounted by a disc, which is turned edgeways to the line for safety, or flatways for danger; and for night signals it is provided with a lantern, with alternate white and red lenses, as usual. The disc is turned by means of a clock-weight descending in the inside of the column, which has to be wound up at intervals of two or three days, according to the number of times the signal is used. The mechanism on which the weight acts is stopped by an electro-magnetic detent, which is connected by conducting wires, like those of the telegraph, to a small battery and manipulating instrument at the station. The manipulating instrument is contained in a small case or cabinet fixed against the wall of the station-master's office. It consists of a handle or lever moving over an arc, half white for safety, and half red for danger—an electric bell, and an indicator or model disc, which always shows the same phase as the main disc on the distance signal. At any moment the station-master, by simple inspection of the instrument, sees how the signal stands, whether at "danger" or at "safety;" if at "danger," the handle is on the red, and the indicator disc shows red; if at "safety," the handle is on the white, and the indicator disc in the office shows white. When he desires to change the signal he moves the handle from red to white, or from white to red, as the case may be, and immediately the bell begins to sound, and continues to sound until the distance signal has turned, and the indicator disc has undergone a corresponding change. In case of any accident happening to the distance signal, of its mechanism being run down, or of its becoming stiff by grit, or rust, or violence, so that the weight cannot turn it, the bell at the station continues to ring, and the station-master can take temporary measures for safety. In case of anything happening to the electrical portion of the apparatus—the battery being exhausted or the wires being broken—the indicator disc shows, like a galvanometer, the absence of electric power, and the bell does not sound on moving the handle. In such case also the station-master can take temporary measures for safety.

This invention was exhibited at the recent conversazione of the Institution of Civil Engineers, and attracted considerable attention.

THE INTERNATIONAL EXHIBITION, 1862.

(Continued from page 270.)

2. *Magneto-Electric Machines used in connection with the Electric Lamp.*

The magneto-electric lights exhibited in Class VIII. illustrate a very important practical application of electricity. The production of the electric light from magneto-electricity is novel since 1851, and this important invention is believed by the writer to be entirely due to Mr. Holmes.

F. H. Holmes, M. (United Kingdom, 2,914), exhibits an effective arrangement of the magneto-electric machine for producing light. The currents are induced by the rapid passage of coils of copper wire wound round soft-iron cores between the poles of powerful horseshoe magnets. The alternately inverted currents produced in this manner are transmitted, by means of a commutator, in one direction only, through the carbon electrodes of the lamp, which has been already described, along with similar instruments, under the head of philosophical apparatus.

The coils, wound on bobbins, eighty-eight in all, are fixed in the rim of a large wheel about five feet in diameter, with their axes parallel to the axis of the wheel. They are arranged in two parallel rings, each containing forty-four equally-spaced bobbins. The centre of each bobbin in one ring corresponds with the centre of the space between two bobbins in the other ring. This wheel is driven at about 110 revolutions per minute. The horseshoe magnets are fixed in a frame round the circumference of the wheel, in three planes or rings of twenty-two each. The two poles of each magnet are in one and the same plane or ring. The distance between their poles is equal to the distance between the bobbins or coils. The magnets in the two outside rings have similar poles opposite one another. The magnets of the inner ring are placed with opposite poles facing the two similar poles of the outer rings. The two outside rings have compound magnets of four plates; the magnets of the inner ring, between the two sets of bobbins, have six plates. The weight of each plate is six pounds. The distance between the successive magnets corresponds to the distance between the centres of the coils, so that each alternate coil has a core magnetized in the opposite direction, but the wires are so connected that the induced currents flow in the same direction. The length of the hollow iron core inside each bobbin is 3½ inches, its external diameter 1¼ inch, its internal diameter 1 inch; two copper wires, No. 9, B. W. G. (0·148 inch diameter), 45 feet long, are wound round each core, and connected in double arc. These wires are equivalent to one wire 0·2 inch diameter of the same length. The core and brass bobbin are split to prevent useless currents outside the coils.

As the wheel revolves each core continually changes its polarity as it passes between the alternating poles of successive pairs of magnets. This change of polarity occurs forty-four times for each coil of each ring; the change is simultaneous for all the coils in one ring, but the moment of maximum change of one ring corresponds to the moment of minimum change in the other. All the coils of each ring are connected in series, and it will be seen from the above description that each ring will induce forty-four distinct currents, each due to forty-four coils during each revolution of the wheel. The coils of both rings are connected with an ingenious commutator, by which they are so combined that the induced currents shall continually pass in the same direction through the carbon electrodes of

the lamp, although passing in four distinct successive combinations through the coils. As already stated, the maximum current from one ring corresponds with the minimum current from the other, and as each current lasts a very sensible time, during which it gradually rises and falls, their combination does not simply produce twice the number of sparks that would be obtained from one ring of coils, but a nearly constant and uniform current, in which the fall of the current from one series of coils is almost exactly compensated by the rise of the current from the other. This effect is said to be very apparent when the currents, first from a single ring, and then from the two combined, are made to record their passage on a moving slip of paper by Bain's electro-chemical process. As each revolution induces eighty-eight distinct currents the machine, when driven at the speed mentioned, sends 9,680 currents through the carbons every minute.

Great pains appear to have been taken to ascertain the best length and section of wire, the best dimensions for the bobbin and for the soft-iron core, together with the speed at which the coils should pass the magnets to produce a maximum effect. At a slow speed the currents will obviously be weak, but if the speed be increased beyond a certain point, the soft-iron cores have not time to acquire their maximum polarities in passing the magnets, and the induced currents consequently fall off in intensity. The bearings of the wheel are double cones, intended to prevent any lateral motion which might bring the ends of the coils in contact with the magnets.

The commutator consists of two massive brass wheels on the main shaft, and four brass rollers resting on the periphery of the brass wheels. The brass wheels are each divided into forty-four teeth. All the odd teeth are in connection with one another, and so are all the even teeth, but the odd teeth of each wheel are insulated from the even teeth. The teeth are separated at the periphery by a broad air space, but a projection of one so fits into a recess of its neighbour, that the rollers on the periphery at the very moment of leaving one tooth come into contact with the next one. One of the rollers is always on an odd, and the other on an even tooth of each wheel. The two ends of the wires of one ring of coils are connected respectively with the even and odd teeth of one wheel, the wires from the other ring are similarly connected with the other wheel. Two of the rollers (one on each wheel) are connected with the two electrodes of the lamp, and the two remaining rollers are directly connected together, and form the link which joins up the two rings of bobbins, first in one way and then in another. The change of rollers from odd to even teeth occurs on one wheel when the rollers of the other are on the middle of their teeth; this change corresponds for each wheel with the moment at which the cores of the corresponding coils are directly opposite the pole of a magnet. The result of this arrangement is to form four different combinations of the coils with the electrodes of the lamp, during all of which the current passes in one direction through the lamp, and continually circulates through the whole eighty-eight coils, all of which conspire to produce a current in the same direction. The large rollers have various adjustments and supports, and the dove-tailed recesses are ingeniously contrived, so that any sparks which occur at breaking contact shall not cause the surface to wear unequally. It is said that when the rollers are perfectly adjusted, and the coils and magnets perfectly spaced, no sparks are visible at the commutator, but sometimes sparks were to be observed on the machine exhibited, showing a certain loss of power.

The visible conversion of mechanical work into heat and light by the agency of electricity in this machine gives an interesting example of the transformation of energy. Mr. Holmes states that the excess of power required to drive the machine when the electric currents are closed is very sensible. One and a quarter horse-power are required to drive the machine when the light is in action.

The self-acting lamp regulator employed by Mr. Holmes does not differ in principle, although very different in detail, from those used in connection with batteries, and any one of the lamps already described might, with more or less success, be used with his machine; but probably none of them would, on the whole, give as good results as his own regulator, which has been already described, and which produced an admirably steady light.

Mr. Holmes' machine and lamp have been in successful operation at Dungeness lighthouse since last June, exclusively in the hands and under the care of the Trinity House. The secretary has kindly informed the writer that the Elder Brethren have not yet satisfied themselves whether the light is generally more brilliant than that at Grisnez, but that careful observations will be made during the winter months, which will enable them to arrive at a more satisfactory conclusion as to its merits.

A. Berlioz & Co., Paris, M. (France, 1,146), exhibit a machine for producing the magneto-electric light, which differs from that shown by Mr. Holmes, chiefly in the absence of the commutator. The coils are arranged in four parallel rings between five rings of horseshoe magnets. There are sixteen bobbins in each ring and eight magnets; the magnets are arranged as in Mr. Holmes' machine, but the bobbins are arranged four in a line, so that they all approach and recede from similar poles of the magnets at the same time. By this arrangement the currents from all the coils always agree in direction, and no commutator is required to prevent their neutralizing one another. The coils are all connected in series, and the two ends connected with the lamp. By this arrangement alternate currents in opposite directions are sent through the carbon points of the lamp, when the coils revolve past the magnets. This rapid alteration of currents passing from a maximum to a minimum, and again to a maximum, must partake somewhat of the nature of sparks, but no intermittence is perceived in the light produced.

Messrs. Berlioz use coils 3·9 inches long; the internal diameter of their hollow soft-iron cores is 1·4 inch, the external diameter 2 inches; round each core are wound eight wires, each one millimetre in diameter, and 16 metres long, joined in multiple arc; this is equivalent to one wire about 0·11 inch diameter, and 52½ feet long. The wire is insulated with cotton and asphalte varnish, and the coils are baked before being used. The magnets in the outside ring are made of three plates, weighing each about four kilogrammes, or 8·8 lbs.; the magnets of the inside rings have six plates. The diameter of the circle passing through the centre of the bobbins is one metre, or 3·28 feet. The machine makes 300 to 400 revolutions per minute; the speed of the coils is therefore nearly double that of the coils in Mr. Holmes' machine, but owing to the different arrangement of the coils, Messrs. Berlioz obtain only about 5,000 currents per minute.

This arrangement is extremely simple. No commutator is required, and no useless sparks can occur, for the circuit is never broken. The light is large and apparently steady, although accompanied by a certain crepitation with occasional flashes; it is to be regretted that the intensity of the light could not be measured, and that the machine could not be tried with Mr. Holmes' lamp. Messrs. Berlioz used Serrin's lamp, and the flashes sometimes seen were perhaps due to a peculiarity of this instrument. The light produced was apparently enveloped by a brownish cloud. It was not possible to determine what effect this cloud had in diminishing the intensity of the light. Messrs. Berlioz, or their assistant, M. Van Malderen, claim to have produced the first electro-magnetic light, in which the use of a commutator is dispensed with. The light was said to be equal to 125 "Becs Carcels," and the machine requires 1½ horse-power to drive it.

E. C. Shepard (United Kingdom, 1,985) exhibits in Class VIII. a magneto-electric machine originally intended for the production of illuminating gas by the decomposition of water. The arrangement of magnets and coils is very similar to that used by Mr. Holmes for his magneto-electric light machine; and it is said that Mr. Holmes' invention of the electric light was the result of an endeavour to discover a profitable use for Mr. Shepard's machine, when it was found that it could not be worked at a profit as a gas generator.

3. *Miscellaneous Practical Applications.*

T. Allan, M. (United Kingdom, 2,850), exhibits the only electro-magnetic engine that requires any special notice. In this arrangement the reciprocating motion of a piston-rod is imitated. This piston-rod has a series of collars, on which soft-iron discs rest loosely, and passes through the centre of a series of soft-iron cores enclosed in a set of electro-magnetic coils, which correspond in number and position to the soft-iron discs. When the piston is in its highest position, the upper disc is very near the pole of the upper electro-magnet, and each successive disc is further off from the pole of its electro-magnet. The current is first passed through the upper electro-magnet, which pulls down its disc and the rod; the current then goes through the next lower electro-magnet; the second disc is now so near its pole as to be strongly attracted, bringing the rod further down, and leaving the first disc behind; the third disc now takes up the work, and the second is left behind; this continues until the stroke is completed by the last and lowest disc. When the rod rises, its collars lift the several discs away

from the electro-magnets into their original position; four of these rods and sets of coils are combined with a four-throw crank, which receives a rotatory motion from them.

L. L. & H. P. Vulliamy, Clapham (United Kingdom, 2,982), exhibit a small model of an electro-magnetic engine, driven by the usual form of suction coil.

H. C. Hurry, Worcester (United Kingdom, 1,892); D. McCullum, Plymouth (United Kingdom, 1,916); and W. Steer, Nottingham (United Kingdom, 1,993), also exhibit electro-magnetic motive engines. These and all other similar machines are liable to the same objection—the enormous expense per foot-pound at which the work is produced.

F. N. Gisborne, M. (United Kingdom, 2,541), and Hemming & Co. [Chevalier M.] (United Kingdom, 2,547), each exhibit in Class XI. an electric target of essentially the same construction. The target is divided into any number of sections required, and behind each section a little ball or hammer is hung touching the plate, or a bolt rigidly connected with it; the plates forming each section are separately supported, so that when one is struck or shaken the others do not move. When any plate is struck its ball or hammer flies back under the influence of the vibration, and for a short time completes a circuit which includes a wire leading to the firing station, a battery, and an indicator, or receiving instrument of some kind. Each plate has a separate conducting wire and indicating needle in Mr. Hemming's target (Lang & Chevalier's patent), although reverse currents to give distinct signals might obviously be employed. Mr. Gisborne has proposed by the use of synchronous apparatus to use only one wire, but no such plan can be practically adopted at present. The conducting wires are generally small copper wires insulated with india-rubber or gutta-percha, and twisted into some form of cable. These targets have been practically tested, and found to answer. Electrically the problem presents no difficulty. Their advantages will, no doubt, be fully admitted in the report for Class XI.

M. Martin de Brettes was the first to propose the construction of an electric target showing *where* it was struck, but it is believed that his complicated arrangement was never carried out. The simple and effective form exhibited in this country is due to Messrs. Lang & Chevalier, and has been very slightly modified in the target exhibited by Mr. Gisborne. Professor Wheatstone used a target to show *when* it was struck in connection with his original chronoscope.

Single examples only are shown of the following miscellaneous applications of electricity:—

Siemens, Halske, & Co., M. (United Kingdom, 2,959), exhibit an *electric log*. Electricity is used to convey a signal to a step-by-step propelment or escapement inside the ship from an ordinary Massey's patent log at, say, every hundred turns of the vane, or at any other given fraction of a knot. An insulated wire is led from the ship to a train of wheelwork contained in an air-tight case, and driven by the vane of the log. This wheelwork makes the contact required at regular intervals, and these are marked by the index of the step-by-step instrument on board the ship. The log, therefore, need never be drawn in to be consulted, and the captain can at any time observe the speed of the ship. It is somewhat to be feared that the stuffing-box through which the connection of the wheelwork with the log is made will either offer so great a friction as to impede its free rotation, or will allow water to enter the case with the clockwork.

C. W. Harrison (United Kingdom, 1,615) exhibits in Class VII. an electro-magnetic hand-printing press. The voltaic current is here used to produce the required printing pressure by means of large electro-magnets with their armatures.

(To be continued.)

THE TELEGRAPH IN SPAIN.

We have from time to time endeavoured to keep our readers *au courant* with the foreign news concerning telegraphy. The difficulty we experience in obtaining information from the continent is increased by the restrictions imposed on the press, and by the inattention of local reporters to matters pertaining to the arts and sciences. War news is prolific, but notices of ministerial or other proceedings, having for their object the promotion and maintenance of peace, are hard to procure. We are indebted to a valued correspondent for the following documents respecting telegraphy, which have been published in Madrid. The measures lately submitted by the minister, Antonio Cánovas del Castillo, and sanctioned by the Queen, will place Spain in immediate telegraphic communication with all other continental nations, will effect a reduction in the tariff for messages, and tend materially to perpetuate the pacific relations of the several governments in Europe.

Ministry of State.

The proposed decree, which the Minister who subscribes submits to the approbation of your Majesty, has the double object of simplifying the service of telegraphs and to offer to the public new and greater facilities for utilizing this means of correspondence.

The receipts in cash from the number of telegraphic messages necessarily imposes upon the Administration certain obstacles, and in the end retards the communications, increasing and complicating the duties of the office. Of necessity the keeping of accounts requires a numerous staff, entirely separated from the proper duties of the department, and subject to all the inconveniences of direct payment from the hand of the sender of messages.

The result of this is that the Treasury is considerably burdened; that frequent disputes arise between the public and the officers of the stations; the necessity of certain requisites on the part of the senders, and the formalities in recovering the messages; the consequent loss of time; and, lastly, the management and detention of funds in departments entirely unconnected by their constitution with such kind of duties.

If the amount of telegraphic messages is not paid in cash, it will be much easier for that branch of the Administration to make the necessary preparations for the transmission of messages—a notorious advantage for the public—and even new channels for the conveyance of telegrams from localities where no stations are established; for the Treasury, an increase in its revenue by the increase of correspondence; for the service, a greater simplicity of proceedings, freed from all unnecessary responsibilities and, in a certain degree, exalted functions: objects which can be obtained by establishing the franking stamps for the telegraphic correspondence.

Such a convenient measure cannot be carried out, in the opinion of the Minister who subscribes, without suppressing certain advantages, more seeming than real, now granted to senders of messages, few of whom enjoy them—foreign to the nature of the telegraphic service, and which impede the rapidity of messages.

The present Administration of this branch, in order to inspire confidence in the senders of messages, does not limit itself to take the precautions required by the service, but lends itself to responsibilities and indemnifications useless to those that claim them, prejudicial to every one else, costly to the State, and never practised in any public department. Anxious, moreover, to obtain the patronage of the public, it goes the length of offering services unconnected with telegraphy to anticipate all kinds of necessities, and from this a multitude of complications and labours which it is necessary to suppress for the future.

If the liberty of correspondence be aspired to, it is necessary, while declaring free from certain obstacles to the public, that the Administration should also be free from an inconvenient tutelage interference, which thwarts its movements, but leave to private interest the care of its own guarantees, as with other services, and do not demand from the telegraph more than its own peculiar business, clear of officious additions, and irregular and unjust burdens, so prejudicial to its exclusive object.

The Minister who subscribes has borne in mind these considerations, when fixing the duties of the telegraphic offices, to deliver messages to the intended recipients within the radius of the town wherein they are established, adding only, when convenient, the forwarding per post, that public service being already established.

From the same grounds proceed the decisions that an acknowledgment of receipt is to be considered a new telegram. That each copy of a message in the same words to different persons in the same place is to be considered a distinct despatch, being so many different services performed for the sender, the perilous and always unsatisfactory personal identification of the recipients; the suppression for the future of a return of money for messages mis-sent or delayed, it being costly and difficult, never satisfactory to the sender, nor in the slightest degree augmenting the accuracy of the service; but, on the other hand, leading to tedious and numerous labours, which have to be paid for by the Treasury. In the introduction of insurance of telegraphs has been sought the only guarantee that can in particular cases be to the interest of the sender; and in regulating the rate of insurance to the trouble imposed, and the advantages to be enjoyed by those desirous

of that security, the character of an exceptional case has been given to it, without, however, conceding any advantages of priority to insured telegrams, inasmuch as exceptional benefits can only be given, so far as they do not interfere with public rights.

There still exists, moreover, a service not rigorously exacted by the public, but which may in exceptional cases be convenient, and which only imposes upon the stations a work of care and attention, that of replies paid for in anticipation. The modifications which, for the retention of this service, have been necessarily introduced in it arise from the indispensable condition of payment by stamps, to be cancelled at the time of presentation, and therefore not in any case returnable.

These alterations can, without difficulty, be applied to the inland telegraphy without any additional preparations but those purely material to its execution. It would only require to make the tariff between the Balearic Islands uniform with that of the Spanish stations in the Peninsula to avoid all unnecessary complication and motive for error; and this, which produces a reduction in the special tariff now existing for the correspondence of the islands, is already comprised in the project.

But if the payment by stamps did not become extensive simultaneous and equal to the international correspondence the object of this reform would be a failure, and would never be effective and beneficial; while amounts, no matter how small they might be, are to be paid in cash, and consequently causing the retention of pass-books and collections, and the officers of the accountant department. As all the difficulties and complications enumerated spring from the international telegraphic treaties, and have been admitted into the internal system solely to render correspondence uniform, the suppression of them in this enforces also their suppression in that sustained with other states. Spain would never be able to arrive at this result without annulling the agreements accepted by her, and without separating herself from other telegraphic administrations where treaties exist. Even on that account a reform of evident convenience ought not to be delayed for consideration of other administrations which are not insensible of the advantages of this innovation, although in theory they hesitate to adopt it; but now, international telegraphic conferences having fallen into disuse, and the term having long expired during the time the last telegraphic treaty was in force, there exists no reason sufficient to stop the application of the reform, and the Spanish telegraphic administration can take the initiative in establishing it without more delay than is necessary for acquainting other states with which treaties have been made, and offering them the consequent and just reciprocity.

The 1st July is fixed for the inauguration of the reform, thus leaving time to make it known to the other nations, and that those may prepare the necessary alterations in their correspondence with Spanish stations. These alterations will leave in force all that is essential in each state, the general basis of correspondence and tariffs.

Unfortunately, there does not exist uniformity of payments of despatches already agreed between France and Spain; there are still nations which keep up telegraphic zones for their tariffs, a system which it would be well to abolish entirely. The Spanish administration will endeavour, as far as possible, by the means which appear most efficacious, that another system should be adopted; but as it is essential with each state to retain or reject it, all future eventualities must be guarded against, not to lose sight of the reform which on its part it establishes, and has made payment by stamps applicable even to correspondence payable by zones, as much as a guarantee and precaution against future persistence in that system, and as a preventive against falling back from the reform, whilst negotiations to render it effective with all other nations are still pending.

This determination demands a declaration which may be transitory, but indispensable, whilst tariffs by zones still exist, that is to put a limit to the fractional charge of telegrams, in order not to increase indefinitely the classes and prices of stamps. For this object, the minimum price of a real has been fixed to cover the excess of cost, which in some telegrams must be paid for any fraction of a real that may be payable. That is to say, as as equity demands a perfect reciprocity be established, not only in the restrictions, but also in the advantages respecting existing arrangements with other states having telegraphic relations with Spain.

Such are, Madam, the objects and basis of the proposed decree, which the Minister who now subscribes has the honour to submit to your Majesty's approbation. If your Majesty deign to grant it, the government will study the means of completing the reform, which is carrying out with other projects of known utility, directed not only to improve the conditions of the lines, but suppress abuses that now disturb much of the correspondence, giving at last to the telegraphic system the organization its importance demands.

Madam, to the R.F. of your Majesty,

ANTONIO CANOVAS DEL CASTILLO.

Aranjuez, 22nd May, 1864.

ROYAL DECREE.

In conformity with what the Minister of State has proposed to me, I have decreed as follows:—

Art. 1. The payment of inland as well as international telegraphic correspondence will be effected through certified stamps, the form and cost of which will be announced in due time.

Art. 2. The texts, which require transmission, can be written on any kind of paper, and presented in the station by any person whatever, or remitted per post, or any other way from any remote part, will be forwarded by the stations, provided they are in accordance with existing regulations respecting their contents and composition, and attached to them the corresponding stamp or stamps to their dimensions, according to tariff.

Art. 3. No despatch whatever will be delivered out of the radius of the locality wherein the station addressed to is situated through any other means than by post; and to forward it through that channel the text which is to be directed must be accompanied not only with the stamps corresponding to the certified telegraph, but also with those of the certified postage from the post office.

Art. 4. The telegrams addressed to localities where there is no station, will be delivered by the last telegraphic office to the post, which will undertake to convey them to their destination as certified parcels, without requiring the seals of the post office. These seals will be delivered to the corresponding post offices by the telegraphic offices that issues them under invoice, and after having been cancelled in the places and districts appointed with the consent of the head departments of both branches.

Art. 5. The seals of all kinds that accompany the despatches as payment of the service of transmission and delivery, will be cancelled at the station that sends them at the time of depositing them in it.

Art. 6. When one sole text is to be addressed to various persons in the same locality, it will be considered for payment as many despatches as individuals pointed in it.

Art. 7. The acknowledgment of the receipt of each telegram will be counted for payment as a new despatch.

Art. 8. Payment will be admitted previous to the return of the answer of the telegrams, effecting it with certified stamps, in accordance with the type specified for answers. These seals will be cancelled as the rest by the station who sends them. If the answer is not returned, or if it should contain less words than those paid for, no return of any kind will be made. If the answer is more extensive than the certified one, the station which sends it will recover in seals the difference between the amount paid and the corresponding one to this new despatch.

Art. 9. When the person who sends the message wishes to certify it, he will use for that object, independent of the corresponding ordinary stamp or stamps to the text, the special seal of certified telegraph. The station that sends it remains answerable to hold at the disposal of the party signing each certified telegram, the channel conveyed until it reaches its destination, and an acknowledgment of its delivery. The certified telegrams will have no preference of turn for transmission.

Art. 10. The private claims for delay or irregularity of telegrams will only give occasion for future enquiry into the causes which have produced the irregularity in the service, for the knowledge of the interested party, and to punish the functionary or functionaries who might result culpable.

Art. 11. In no case the identification of the sender of the message will be required, though he may offer it or if any one should claim it.

Art. 12. The managers of post offices, in localities wherein railway stations and government telegraphs exist will make special separation of the parcels for the telegraphic service, so as to be delivered instantly to the telegraph stations after the arrival of each train.

Art. 13. The same telegraphic tariff will regulate the inland correspondence and that of the Balearic Islands.

Art. 14. The general administration of the branch will give immediate cognizance to the managers of the different states bound to Spain by telegraphic treaties, of that part of the preceding arrangements which will cause alterations in the present form of the correspondence between the different countries, and will endeavour by all means which it may consider convenient to harmonize the international telegraphic service.

Art. 15. The same administration will put itself in communication with the administration in Portugal, to establish an uniform tariff between the nations, and will invite at once the other nations to suppress the telegraphic zones.

Art. 16. The accounts for the international correspondence will be carried as at present, but the liquidations and balances that may result, the General Administration of Telegraphs will acquaint the Finance Minister, so that he may dispose of those funds as he thinks proper.

Art. 17. In the meantime that the uniformity in the tariffs amongst the different states united by telegraphic correspondence is in abeyance, that which is sent from Spain to the nations still preserving their tariffs per zones, the amount will be collected as it is agreed, but in certified stamps and in entire reals, counting as a real every fraction of a real which may result in the rate of every despatch.

Art. 18. The Minister of State will enter into an arrangement with the Exchequer to decide upon the issuing and convenient cost of the special telegraphic stamps, and will adopt such measures as he may consider necessary to carry out what is ordered in the preceding articles.

Art. 19. The General Board of Telegraphs will immediately adopt the necessary measures, so that from the 1st of July the preceding resolutions may be carried out.

Art. 20. All the measures in opposition to these presents are therefore annulled.

Given at Aranjuez, on the 22nd May, 1864.

I THE QUEEN.

To the Minister of State for Home Affairs,
Antonio Cánovas del Castillo.

The provincial deputation of Seville, recently invited to take part in the development of the Submarine trans-Atlantic Telegraph which is to unite Europe with America through Portugal, has been found disposed in favour of the project. It is to be hoped that the deputation of Corunna, to which one of the most important and influential telegraphic societies of the capital will soon apply, will also answer the appeal in a noble and generous manner, to assist in carrying into effect the laying down of the cable, to start from Falmouth and terminate in Corunna, putting this nation in direct communication with Spain, freeing themselves from the interference which France exercises at present. The deputation of Corunna, in which we are told are to be found liberal, clever, and independent members, will not only embrace, but will give an impetus to this measure of importance.

One of the weekly scientific meetings of the telegraphic body took place on the 30th of May, at its club in Madrid, and Mr. Felix Garcia Rivero expressed himself in so satisfactory terms upon the submarine telegraph, that he left nothing untouched in his pleasing and honest speech.

Completely recovered from the illness under which he has been suffering of late, Mr. Mathes, an active and clever functionary, has taken charge of the general management of telegraphs in Spain.

ON THE PATENT LAWS.

(*Continued from page* 272.)

The following communications were received by the Secretary of the Society of Arts from members who were unable to attend the discussion on Mr. Webster's valuable paper, and will be perused with interest by many of our readers :—

Mr. HENRY COLE, C.B., writes as follows :—

At the adjourned meeting of the Society to discuss the Patent Laws, I request that you will have the kindness to read this letter as a substitute for my presence. I feel it somewhat of a duty not to be silent, having taken an active part years ago in promoting the reform of the Patent Laws upon the principle sanctioned by a Committee of the Society, whose three published reports I was entrusted to prepare.

In 1849 a numerous Committee of noblemen and gentlemen* was appointed by the Society to promote "Legislative Recognition of the Rights of Inventors." The opening paragraph of the first report of that Committee was as follows :—

1. A British subject has no rights of property whatever in that intellectual labour which produces invention or scientific discovery, excepting such as he can obtain by petition from the Crown. He may have bestowed years of mental exertion and manual toil in perfecting a discovery most beneficial to mankind, still he is not in the position of being able to claim even the recognition of the fruits of his labour as his own. He must become a petitioner for the right to the Crown, which is absolute and irresponsible, and may refuse it without any power whatever of appeal. Many and well-settled as are the rights of British subjects compared with those of other nations, the suppliant inventor has no rights of his own in his invention.† The inventor in France, in America, in Holland, and in Belgium, even in Austria and Spain, has his rights recognised by declared law; but the Englishman has none. By passing through a series of formulas, so antiquated that the origin of them is lost in the obscurity of past centuries—so empty and frivolous that common sense revolts at them—so numerous that they can hardly be reckoned accurately—so intricate that every one seems a pitfall to discourage scientific invention to the utmost—so inexplicable that the greatest diversity of opinion obtains in interpreting them—so costly as to place scientific intelligence wholly within the power of capital; an inventor may at last obtain a mere recognition of his right, which he is then at liberty to protect as he may be best able.

2. This Committee brought before the public, for the first time, a recital of the thirty-five stages which it was necessary, at a cost of about £100 in fees only for England, to pass through to obtain a patent; and Mr. Charles Dickens, in a most humourous paper, entitled "A Poor Man's Tale of a Patent," in his *Household Words*, described how one Thomas Joy had

* The Committee consisted of the following:—The Marquis of Northampton; the Earl of Radnor; Sir John P. Boileau, Bart.; Sir J. J. Guest, Bart., M.P.; the Right Hon. T. Milner Gibson, M.P.; Henry T. Hope, Esq., M.P.; Samuel M. Peto, Esq., M.P.; Sir James Anderson, Glasgow; George Brace, Esq; Henry Cole, Esq.; Charles Dickens, Esq.; J. H. Elliott, Esq; John Farey, Esq., C.E.; P. Le Neve Foster, Esq., M.A.; Charles Fox, Esq., C.E.; Wyndham Harding, Esq, C.E.; Edward Highton, Esq.; Captain Boscawen Ibbetson, K.R.E.; Owen Jones, Esq.; Herbert Minton, Esq., the Potteries; R. S. Newall, Esq., Gateshead; Dr. Lyon Playfair, F.R.S.; Richard Prosser, Esq, Birmingham; Dr. J. Forbes Royle, F.R.S.; W. W. Rundell, Esq., Falmouth; Archibald Slate, Esq, Woodside, Dudley; J. Jobson Smith, Esq, Sheffield; Professor Edward Solly, F.R.S.; Robert Sutcliffe, Esq., Idle, Leeds; John Sylvester, Esq.; Arthur Symonds, Esq; Professor Bennet, Woodcroft. Secretary, George Grove, Esq.

† "There is not any clause or enactment by which the subject can demand them as a right. This great encouragement to industry, this fruitful source of wealth, is still the free gift of the Sovereign. It emanated from Her Majesty, as the patron of the arts and sciences, at the humble request of her subjects; and it is as a gracious favour that she extends this royal protection to the inventor."—*Godson on Patents*, p. 21.

perfected a model, and wanted to patent it; came to London; petitioned Queen Victoria; declared before a Master of Chancery; went to the Home Office; got his petition signed by the Home Secretary; took it to the Attorney-General; paid four pound four; "Nobody all through ever thankful for their money, but all uncivil;" back to Home-office; got a warrant; sent to the Queen; Queen sent warrant back; Home Secretary signed again; went to Patent-office for a "Draft of the Queen's Bill" and a "Docket of the Bill;" two copies engrossed, one for Signet-office, one for Privy Seal-office; engrossing, stamping; again to Attorney-General; again to Home-office; again to the Queen; then to the Signet-office; then to Lord Chancellor; then to Privy Seal; then to Clerk of Patents; then fees to Lord Chancellor's Purse-bearer and to Clerk of Hanaper, and to Deputy Clerk of Hanaper; again fees to Lord Chancellor; and lastly, fees to Deputy Sealer and Deputy Chaff Wax! Pleasant processes to numerous interests—law and others. All this rubbish the Society cleared away.

3. The Great Exhibition of 1851 gave a great blow to this antiquated system, and a special Act of Parliament was obtained, which enabled inventors to exhibit without the intervention of Hanapers and Chaffwaxes. Then a Committee of inquiry in the Lords sat, and an Act was passed, based upon many of the most important principles advocated by the Society, and in accordance with the practice more or less adopted by other European countries and the United States. I need not describe them: they are stated in the third report of this Committee.

4. There has now been ten years' experience of this Act, and everybody, without exception, advocates the amendment* of the system; as Mr. R. Wilson said in his excellent and practical speech, "Either improve this system or give up the patents altogether," whilst there is a strong and growing party which desires its repeal and the abolition of patents. A commission, consisting of legislators, lawyers, and others, are investigating what is to be done, and, appropriately enough, the Society again discusses the subject.

5. Certainly the problem is most difficult, and not to be hastily solved. It is easy, if you are convinced, to say, "Away with all patents, and no monopolies; leave manufactures alone and to manage for themselves;" and I confess I find myself inclining more in that direction than towards tinkering at minute administrative legal details.

6. Yet, on the question of principle of patents, I hesitate to say confidently that Adam Smith and Bentham, John Mill and others are in error, and that the practice of other countries is wrong. But the discussions which have taken and are taking place, as well as the experience of the last ten years, make, to my mind, some things in this matter quite clear. I have no interest whatever in any patent. I claim to have been a reformer of the old patent laws. I am not a patent agent or a lawyer, and I think I am quite unprejudiced and dispassionate on this subject.

7. It is clear to me that copyright in authorship or artists' work is quite

* The following were the heads of a Bill recommended by the Society in 1852, and it will be seen that many of the evils now complained of would not have existed had the recommendations been fully adopted:—

Resolutions passed to form the Heads of a Bill.

1. That everything in respect of which a patent may now be granted should be registered.
2. That the benefits afforded by Registration should extend to the United Kingdom of Great Britain and Ireland, and the Channel Islands.
3. That the Registration should be considered merely a record of claims, and not as any determination of rights between parties.
4. That it should be competent to any Inventor to make disclaimers and to rectify errors in his Specification at any period.
5. That Registration of Inventions should be obtainable for a period of one year on payment of £5, and should be renewable for four periods of five years each, on payment of £10 at first renewal; of £20 at second renewal; of £50 at third renewal; and of £100 at fourth renewal. [The principle of renewed payments is proposed as a means of testing whether an invention is in use, and of removing useless inventive rights that might otherwise be obstructive of improvements.]
6. That there should be penalties for using the title of "patent" or "registration" where none has ever existed.
7. That the present tribunals are insufficient for the trial of subjects of design and invention.
8. That it should be permitted to commence actions for infringement of the rights of Inventors in the County Courts.
9. That inasmuch as, contrary to expectation, very little litigation has been created by the rights conferred by the Designs Act of 1842 and 1843, this committee is of opinion that a fair trial should be given to the working of the proposed system of Registration of Inventions before any special tribunal to determine inventive rights is substituted for the existing tribunals.
10. That any tribunal before which proceedings are commenced should have power to refer any case for report and certificate to the Registrar, assisted by competent and scientific persons.
11. That upon the illegality of the Registration being established by the judgment or order of any competent tribunal, the Registration be cancelled.
12. That there should be only one office for the transaction of business connected with the Registration of Inventions, and the payment of fees in respect thereof.
13. That every person desiring to register an Invention should submit two copies of the Specification of his claim, accompanied, in every case where it is possible, by descriptive drawings.
14. That the mode and procedure of Registration should be regulated by the Board of Trade, subject to a report to Parliament.
15. That an annual report of all Specifications registered, with proper indices and calendars, should be laid before Parliament.
16. That a collection of all the Specifications should be made, calendared, and indexed, and deposited for public information in the British Museum.
17. That it is highly desirable that such a collection should be printed and published.
18. That the surplus profits, after paying office expenses and compensation, should be directly applied to some public purpose connected with invention, but not carried to the Consolidated Fund.

distinct from patent right in invention, or the "first finding" of a thing. Minds, however, alike, dwelling on the same thoughts, could never utter them or represent them in the same way identically. Mr. Webster says, "the subject of copyright is one specific combination of words, letters, and lines, in this respect similar or analogous to the specific combination constituting a machine." The fallacy of this is apparent when we put Shakespeare and his "Hamlet" as "similar or analogous" to W. E. G. and his "Ærial machine," or R. D. and his "Hair brushes rotatory," or W. C.'s "Lubricating apparatus," as registered in the Society's last *Journal*. But inventors seeking to find a something would most probably each one find that identical something at the end of their race. They are like huntsmen—Reynard is there—somewhere—and the first seizes the brush, which the second or third might have got by happy accident.

8. It has been hitherto held to be good public policy that the first finder shall have a limited monopoly of his invention against other seekers and finders, on condition of his honestly making it fully public.

9. Everybody agrees that the finder does all he can not to keep this part of his engagement. His specification is made as dark as possible. Can you compel him to make it clear and definite? Perhaps so, but it is difficult. Perhaps a public registrar might usefully be appointed to determine if the inventor did or did not state in a given form, clearly and unmistakably, what his invention was.

10. I am opposed to Mr. Webster's opinion that "Patents should *not* be granted as of course, but some check be placed on their indiscriminate issue by a preliminary inquiry and report." I don't wish to see a Pope for patents, or any compulsory tribunal attempting to decide if the invention be one or not. I doubt its competency and authority. I am sure it would give little satisfaction, and certainly an appeal against its decision would have to be allowed, which might be good for lawyers, but certainly not for inventors. The onus of the proof of the invention I think must rest solely with the inventor. Like all other possessors of rights, the inventor himself must defend his own if he care for it.

11. One great merit of the existing law is that it extinguishes frivolities. Mr. Hawes has shown that out of 3,000 patents, only 100 sought to exist for seven years. "Only 100 out of 3,000 are worth £100 at the end of two years."

12. If it be determined to maintain the principle of a Patent Law, then the preservation of this principle of successive stages seems to be most important, but I think the time of duration of the right as well as the cost should be greatly reduced.

13. Let the "first finder" or inventor have a right of registering that he claims to be so. Compel him to register his claim as distinctly as possible. Allow of no evasions. Pay a public officer to keep him up to the mark. Allow his claim to stand good for twelve months and no longer. This period, I think, would be sufficient to enable him, not, perhaps, in some few cases, to *perfect* his invention, but to keep a-head in the market of other claimants, and to find, if necessary, the capital to go on with it; for it is generally admitted that the first finder has to find, besides his invention, the capitalist, who works the thing found. As Dr. Collyer said, "Men who had money did not, as a rule, devote themselves to invention."

14. It may be said that so short a period of monopoly is not long enough to attract capital. I don't believe it. Capital will obey the usual laws of self-interest, and it is not requisite that Parliament should give it monopolies or protection. It can take care of itself.

15. It has been proved, I think, that no very great discoveries can be traced to the monopoly granted by the Patent Laws. They go on quite independently of charters or legislative laws and such like artificial conventions. I have arrived at the belief that the progress of inventions, either great or little, would not be arrested in the slightest degree if Patent Laws were abolished. Philosophers don't want the monopoly. Competitors for "first findings" may—and it may be right to give it, although it is admitted that the monopolies granted lead incidentally to great nuisances, undoubtedly hindering other competitors.

16. The question resolves itself to this: Is it right public policy to encourage first finders or inventors to hunt for things, to register publicly such findings, and, in return for such public registration, to acknowledge their claims to a right to the "first find" for a very limited time? and I come to the conclusion that under present circumstances it is. Such policy may lead to the abolition of even the very limited monopoly proposed. If it do, it will be an easy transition—better, I conceive, than a violent and absolute revolution, like the total abolition of patents. If it do not, then the limited monopoly will remain, in accordance with public convictions of its public utility, but very limited in duration. The right of monopoly should, I think, be obtained easily, and at a cost sufficient and no more to pay the expenses of a proper registration. Experience has shown that the present fees are merely a tax, which has not even yet been applied to erecting a creditable Patent Library or Museum for Inventions, things of great value and public interest apart from the policy of patents.

(*To be continued.*)

FRENCH TELEGRAMS.—It is announced that on and after the 1st July next, the rates for telegrams between France and Bavaria will be from 3f. upwards.

THE AMERICAN PATENT COMMISSIONER ON THE POLICY OF PATENTS.

(*Continued from page 274.*)

I NOW recur to the first and most important question, whether the patent policy has actually increased the industrial resources of nations.

It is grateful to refer to the testimony upon this point given before the committee before referred to by intelligent practical men thoroughly familiar with the operation of the patent laws and the condition of the arts in Great Britain. Mr. Carpmael, a patent agent of great experience, in reply to the question—"Are you of opinion that the present patent law might be safely repealed altogether, and inventions deprived of all privileges of protection?" replies, "I can only say that I can see no inducement to an inventor to come forward to benefit the manufactures of the country, unless you give him some reward. Looking through the history of the whole of the manufactures of this country, you will find that all the steps have been founded upon patents, from the earliest date up to the present time. Take any branch, whether it be the cotton manufacture, the steam-engine, the manufacture of flax or wool—in the case of every one, if we trace the history of it through, which I should be happy to do if it were necessary, it will be seen that the whole system is based upon patents. Paper-making is the same, and so in every branch that I remember."

Being asked, "Can you without difficulty point out a certain number of very important inventions, which were preceded by such costly experiments that they could not have been carried out without the patent law?" Mr. Carpmael says: "Watt, in the case of the steam-engine, was seven years before he got the first engine to work efficiently. In the case of Arkwright's machine for spinning cotton, he was several years before he got efficiently to work. In the case of Crompton the same; in the case of Hargraves the same. Then, in regard to combing wool by machinery, and the first power-loom by Cartwright, he did not succeed in getting practically to work for many years, and he was rewarded by Parliament for what he had done, because he had not been remunerated in the working of his patent. The paper machine was worked out by a series of costly experiments, which never would have been entered upon but for the patent laws of the country. In this manner might I go through all our manufactures; indeed, in no instance has any manufacture grown into importance in this country except by a series of costly experiments and costly machinery, carried on for many years in the hope of deriving benefit through a grant of letters patent."

Mr. Webster, the well-known writer on patent laws, stated before the committee: "I am quite sure of this, that if any person who may be disposed to think that patents should be done away with, comes to examine the way in which particular manufactures have been built up by reason of the large amount of capital which has been thrown into them, in reliance upon the action to be obtained by means of the protection given for a short time, he will be very much surprised. In some of the most successful inventions of the present time, it will be found that the first patent effected little; but, in attempting to work this out, further improvements were made, and fresh patents obtained, so that by the protection which has been given to different stages of the invention, and the quantity of capital which has been laid out upon it, the invention has been perfected and introduced, and made useful to the public in a time within which it never could have been done but for the money which has been employed upon it, in reliance upon the protection of the patent. The whole of our experience of cases before the privy council is proof of that, and leads to the conclusion that many inventions would never have been introduced at all without such protection; and no man, so far as my knowledge of manufactures goes, would have ventured upon those experiments had it not been from some such inducement as the reward offered by the patent law."

Mr. Bennett Woodcroft, the accomplished superintendent of the Great Seal Patent-office in England, under the Commissioners of Patents, to whom more than any other person is due the publication of the specifications and drawings illustrative of all the patents granted in England since 1617—a work which may be justly regarded as one of the proudest monuments of British genius—has added to the many obligations conferred upon this office by presenting to it, within the last year, a series of engravings executed in the highest style of art. Their subjects can be best described in his own words: "Actuated by a sincere respect for mechanical genius, and a warm admiration of its productions, I have collected all the known portraits, eight in number, of the *ten mechanicians* whose inventions laid the foundation, raised the superstructure, and now secure the continuance of the cotton manufacture, the most marvellous for its extent and effects that ever employed the ingenuity of man."

Mr. Woodcroft, in a memoir which he has published containing brief biographies of inventors of machines for the manufacture of textile fabrics, observes that in looking at the progress and magnitude of the cotton manufacture, surprise is excited at the simple construction of the few machines which have produced such wonderful results, "at the lateness of their revelation and their tardy adoption." And he appositely applies to those works the words of Milton:—

> "Th' invention all admired, and each how he
> To be th' inventor missed; so easy it seemed,
> Once found, which, yet unfound, most would have thought impossible."

The ten mechanicians to whose inventions the results produced in the

cotton manufacture are by Mr. Woodcroft mainly attributed are—Kay, who was inspired to run the shuttle on pulleys, and impel it by a short lever attached to a string, by which one weaver was enabled to do the work of two or three; Paul, who taught a method of spinning a hundred or more threads at once; Arkwright, who reinvented and revived roller spinning; Hargraves, who invented the jenny, which drew sixty or seventy threads at once; Crompton, who invented the *mule* (so called because it combined Paul's and Hargrave's inventions); Radcliffe, the author of the improvement in sizing or dressing the whole of the warp before it was wound upon the beam, thus removing the grand difficulty then existing in the art of weaving; Cartwright, who brought forth a loom which would weave cloth by a mechanical, instead of a manual motor, and thus quadruple the power of the weaver; Jacquard, who invented the apparatus to which his name is given for selecting the warp threads, which superseded the service of the draw-boy at the loom; Roberts, who made the mule of Crompton automatic, or self-acting; and Heilmann, who, from observing his daughters comb their hair, conceived the machine for combing cotton and wool, ever since in universal adoption.

Mr. Woodcroft thus states the result in Great Britain alone, produced mainly, as he considers, by these ten inventions:—In 1760, at the accession of George III., the entire value of cotton goods manufactured in England was about £200,000 a-year. In 1772 British calicoes were made to the number of 50,000 pieces. In 1816 upwards of 1,000,000 pieces were manufactured. In 1750 the population engaged in the cotton manufacture was about 20,000. In 1801 the persons engaged were about 80,000. In 1823 there were 10,000 steam-looms in Great Britain. In 1862 their number was 399,992, driven with a power of 294,000 horses, and employing 451,000 workpeople in 2,887 factories, containing 30,387,457 spindles. Every one of the ten inventions which have produced these marvellous results was protected by patents; each inventor was stimulated by the reward which this protection opened to his hope, if not his fruition, and, without the prospect of appropriating to himself wealth and honour, would have shrunk from the labours of creating and introducing his invention. Granting, as is quite probable, that the individual importance of these men in relation to the cotton manufacture is somewhat exaggerated, and that the credit given to them should be shared with the eight hundred men who have taken out patents for improvements in this manufacture, it is no less true that the whole system of the manufacture of cotton in Great Britain is founded upon patents.

Illustrations—less striking it may be, but not less convincing—of the beneficial influences of the protection afforded by patents can be found in the history of the industrial arts in this country. I will point to a totally different branch of manufacture which had its undoubted origin, and has attained its perfection, in the United States—the manufacture of india-rubber goods. The facts are obtained from records in this office and reports of committees in Congress. India-rubber was introduced into France in 1776. Dr. Priestley says, that in 1791 he saw a specimen of the gum at a stationer's, where it was used to erase pencil-marks—hence its name. In 1823 five hundred pairs of shoes, made by the natives in South America directly from the exudations of the gum-bearing tree, were imported into this country, and sold at Boston. In the years 1832, 1833, 1835, and 1836 several manufactories were established in New England for making india-rubber goods.

Upon their introduction into market, it was found that the goods became clammy and sticky when exposed to heat, and were stiffened by the cold. They were, therefore, useless. In consequence of these defects, in 1839 all the companies and individuals engaged in the manufacture were ruined. The manufacture was utterly prostrated. At this time a simple workman in Connecticut, named Hayward, who had undertaken to carry on this manufacture by himself—who, to use his own words, hired the shop he worked in—and whose only income from the uncertain profits of his business was about 500 dols. a-year, sought day and night to discover some substance which might be combined with the india-rubber and cure its defects. Absorbed in the search of what to him was the philosopher's stone, "he dreamed at night," as he asserts, that the desired solvent was sulphur. He combined the rubber with sulphur, and to his delight discovered that the defects in the goods were almost wholly overcome. He had miraculously, as it were, discovered a substance which combined chemically with the rubber, making, in fact, a sulphuret of rubber—indeed, a new substance, whose structure is fibrous like horn, whereas the structure of rubber alone is granular, or molecular. He obtained a patent for his discovery, but being heavily in debt, and perhaps unable to conceive of the vast consequences which would result from his invention, he sold the right to his invention for a mere pittance to Mr. Goodyear. The latter experimented upon the new compound discovered by Hayward, and discovered the art of vulcanizing it. This invention is thus described by Mr. Webster, in his great speech at Trenton:—"The great peculiarity of this vulcanizing process is this: If you take a compound of sulphur and rubber in a dry state and grind and mix them together, and apply heat, the consequence is that the substance softens and softens as the degree of heat increases, until it reaches a certain height in the thermometer, say 212° Fahrenheit and along there, a little more or less. Well, anybody," says Mr. Webster, "who ever tried the effect to see what would be the operation upon this compound, and finding that it ran up to a great degree of heat, softening and rendering it more and more plastic as the degree of heat was augmented, would naturally be of the opinion that if the heat was carried still higher the whole substance would melt. But Mr. Goodyear, as the result of untiring experiment, found out that, although the application of heat produced a melting effect upon this compound, rendering it more and more plastic and soft as the degree of heat augmented, yet when the heat, going on, had got up to a certain much higher degree, its effect was the reverse of what it had been, and then the rubber composition commenced to vulcanize and harden, and in fact to make metallic the vegetable substance." The result of the two inventions is thus stated by Mr. Webster:—"It introduces quite a new material into the manufacture of the arts, that material being nothing less than elastic metal. It is hard like metal, and elastic as pure original gum-elastic. Why, this is as great and momentous a phenomenon occurring to men in the progress of their knowledge, as it would be for a man to show that iron and gold could remain iron and gold, and yet become elastic like india-rubber." Mr. Goodyear obtained a patent for his discovery, and granted licenses to manufacture under his and Hayward's patents. The manufacture at once revived. Twenty years afterwards the yearly sale of goods created by these inventions in the city of Boston alone was set down at 2,500,000 dols. Thousands of operatives are employed in their manufacture. The uses to which the vulcanized rubber is applied are innumerable, and new uses are discovered every day. Waterproof shoes, clothing, tents, pontoons, blankets for soldiers—invaluable as they have been proved in our service, preventing the loss of thousands of lives, and promoting the health and comfort of the soldier to a degree beyond estimation; buckets, life-preservers, mail-bags, car-springs, suspenders, pencil-cases, combs, boxes, are only a few of the countless articles made, specimens of which may be seen in the beautiful collection deposited by Mr. Goodyear in the saloons of this office. There is probably not a family in the country that does not use these goods, and there is hardly an instance on record in which inventions have within so short a period become so essential to general comfort and convenience.

It is unnecessary to say that this great manufacture was founded upon the stimulus which the patent privilege gave to the inventors, and the protection which the patents have given to the manufacturers.

I have spoken of the great spinners and weavers who have carried the cotton manufacture to its great perfection in Great Britain. An invention in the class of textile manufactures has been made by an American, which equals in ingenuity anything which has been accomplished in Great Britain or France. The history of the invention proves that it would not have been introduced without the protection which the patent afforded, and there is precise evidence on record of the saving in money which it has effected for the consumers of the country. Previous to 1842 all three-ply and ingrain carpets were woven in hand looms, the motive power being furnished by the weaver. Numerous and costly experiments to weave ingrain carpets by power-looms had been made in England, but had proved unsuccessful. Mr. Erastus P. Bigelow, of Massachusetts, in 1842, conceived of a series of devices for making the carpet loom automatic, so that the costly labour of men might be dispensed with, and the whole process of weaving might be conducted by girls and boys. After laying his plans before many manufacturers, without obtaining their approval, he succeeded in engaging the attention of the treasurer of a manufacturing company in Lowell, who had the intelligence to see the importance of the undertaking, and to understand the grounds of its probable success. Through him he made an engagement with "the Lowell Company," which, in consideration of the exclusive right to use all his inventions then or afterwards made, so far as they could be applied to the weaving of ingrain carpets, agreed to pay the expenses of putting a trial loom in operation, and if that proved successful, to build a power-loom mill, and to pay Mr. Bigelow a certain patent rent per yard upon all carpeting woven during the existence of the patents which Mr. Bigelow was to take out for his inventions. The trial loom proved successful, and the company proceeded to erect mills to manufacture carpeting under Mr. Bigelow's patents. The cost of these works was many hundred thousand dollars, the fixed capital of the company in their carpet works being $978,956. This vast outlay was made, and in fact the whole improvement was based, upon the protection given by the exclusive right under the patents. The invention was of such a character that it could be developed, tested, perfected, and made practically useful only by the expenditure of a vast capital. The only security for this outlay, which no individual could have made, was the protection of the patent. The company were careful to secure the right to all future improvements which the inventor might make. Encouraged by the certain though moderate reward offered by his arrangement with the company, the inventor continued for four years after the first loom was devised, to add new improvements which were protected by five more patents; and it now presents a machine which is admitted to be unsurpassed by anything which the mechanical genius of man has ever devised. The benefits which this invention has conferred upon the manufacturing company, the inventor, and the public, are precisely shown by records in this office, The "Lowell Company" granted to the "Hartford Carpet Company" a license to use these inventions, the use being confined to these two companies. The profit in the carpet department, in the Lowell Manufacturing Company, from October 31, 1859, to April 30, 1863, was $687,801 41c. The total dividends of the Hartford Carpet Company from January, 1855, to July, 1863, were $1,009,649 50c. The par value of the stock, $100 per share. The market value, $155 to $160 per share.

The total receipts of the inventor from his royalty have been $50,432 12c.

The benefit to the public by this invention is, first, the production of superior goods, the texture of the power-loom carpeting being more uniform, the selvage more even, and the matching of the figures more perfect. The actual saving to consumers is thus calculated:—Prior to the introduction of the power-loom, the Lowell Manufacturing Company paid, as wages for weaving by the hand-loom the description of carpeting known as two-ply, $11\frac{3}{4}$ cents per yard, and for three-ply, 25 cents per yard; whereas, with Bigelow's power-loom, they only pay for weaving the former article, $2\frac{57}{100}$ cents per yard, and for the latter, $2\frac{83}{100}$ cents per yard; thus showing a saving by the power-loom in wages paid for weaving of $9\frac{18}{100}$ cents per yard for two-ply, and $22\frac{17}{100}$ cents per yard for three-ply, being an average of $15\frac{67}{100}$ cents per yard. But the saving in wages is partly neutralized by the more costly repairs of the power-loom machinery, and interest on the larger investment of capital required therefore, so that the average net saving by the power-loom is estimated at ten cents per yard. Accurate returns from the mills of the Lowell and Hartford companies up to April, 1863, show that the number of yards of carpeting woven upon looms was 25,964,185 yards; thus the saving to the people by this invention has been two million five hundred thousand dollars. That the saving in the price of manufacture of carpets has accrued to the consumers is evident from the fact that at the time Mr. Bigelow's invention was introduced the wholesale price of the best quality of two-ply carpeting was from eighty-five to ninety cents per yard, and of three-ply from one dollar and thirty, to one dollar and thirty-three cents per yard; whereas, in 1860, the former description of goods, power-loom wrought, of a better quality than the hand-loom wrought, sold for from seventy to seventy-two and a-half cents per yard, and the latter from ninety-five to ninety-seven and a-half cents per yard, making an average reduction of over twenty per cent. It is worthy of observation that the ingrain carpets are used not so much by the wealthy as the middle classes. They give comfort and attractiveness to the homes of the people, and thus this invention, originated and introduced by the patent policy, has had a sensible effect in ameliorating and refining society.

CORRESPONDENCE.

THE PERSIAN GULF TELEGRAPH CABLE.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—In your journal of the 28th ult. there appeared a most interesting account of the successful telegraphic operations in the Persian Gulf. The whole proceedings appear to have been conducted in the most scientific and systematic manner, from the commencement to the completion thereof, and the greatest credit is due to Lieut.-Col. Stewart, and Sir Charles Bright and his able and experienced staff, for the manner in which they performed the arduous and difficult duties upon which they were engaged, and more especially as these duties had to be performed under considerable disadvantages from the nature and character of the Gulf and its inhospitable shores, and also the remoteness of the scene of their labours from any place where assistance could be obtained in case of accident or failure.

Only one untoward event occurred during the whole operation—the sudden cessation of the continuity in that portion submerged between Bushire and Fao. The cable being laid in comparatively shallow water, not much difficulty was experienced in restoring the communication, but what concerns the public in the matter is what if such a cessation had taken place in deep water, such as the Atlantic for instance, where repairs could not have been effected. The nature of the injury is a singular one, and is thus described:—"*It was found that the wire only was affected, its gutta-percha covering and the outside casing of iron wire, &c., remaining intact.*" Was not the outer iron casing elongated by excessive strain, and thereby breaking the copper conductor, or was the fracture of the copper owing to a defect in quality or in a joint? It is further stated that "*When the steamer came over the exact spot and the broken part of the cable began to be racked off the ground, the electric current began to flow through it again as if it were perfect. This was the result of the bending of the cable as it left the ground, which caused the broken ends of the wire to come again into actual contact.*"

Was it not the result of the release of the cable from overstrain that brought the ends of the wire together, or, in other words, the contractile force of the iron sheathing? As the question is one of the greatest importance with respect to the approaching attempt to submerge an Atlantic cable, I am sure that any further information upon the subject would be thoroughly appreciated by many besides your obedient servant,

June 4th, 1864. ONE INTERESTED IN SUBMARINE TELEGRAPHY.

THE GLOBE TELEGRAPH COMPANY.—The above company's bill for parliamentary powers has passed. It was vigorously opposed by the Universal Private Telegraph Company, but fortunately for telegraphic interests, unsuccessfully. The Wilde instruments are exceedingly ingenious, simple, and effective in their action, and, in our opinion, superior in every respect to those of Wheatstone.

PARLIAMENTARY NEWS.

THE CANADA AND PACIFIC TELEGRAPH.

Mr. S. AYTOUN asked the Secretary of State for the Colonies, if he could say when the returns relative to Customs Duties (Canada), ordered on the 5th of May, and the return relative to the Canada and Pacific Telegraph, ordered on the 10th of May, would be laid upon the table, and what was the reason that there had been so long a delay in doing so.

Mr. CARDWELL said he was sorry for the delay that had occurred in the production of the parliamentary papers, which was owing to the circumstances of their being contained in a large number of different volumes. They were, however, now in the hands of the printers, and he hoped they would be shortly in the hands of hon. members.

TELEGRAPHIC NEWS.

PORT NATAL.—The telegraph line to Maritzburg was being constructed at the date of the departure of the last mail from the Cape, and it was expected that the whole line would be open for business in a few days.

PERSIAN GULF TELEGRAPH.—Col. Stewart telegraphs from Mussendom, under date the 8th ult., that telegraphic communication with Bagdad, viâ Teheran, will be completed very early in July. The land line was completed on the 7th ult. from Bushire to Kaycroon, 100 miles, including the most difficult mountain passes on the whole line.

THE ATLANTIC TELEGRAPH COMPANY.—We had an opportunity a few days ago of testing electrically a portion of the new cable now in course of manufacture at the works of the Telegraph Construction and Maintenance Company, Limited, Wharf-road, City-road. We found its insulating properties to be most satisfactory; indeed, superior to any core which we ever had an opportunity of testing. The arrangements adopted by Mr. Willoughby Smith, the company's electrician, for testing, appeared to us of the most complete character, and every facility was afforded us in our examination of the apparatus and the cable.

THE TELEGRAPH IN SPAIN.—In another portion of these columns will be found some interesting particulars with respect to the opening up of telegraphic communication in Spain. The interest which has ever been manifested by the Minister, Senor Antonio Cánovas del Castillo, in the establishment of a system of telegraphy, and in the development of the resources of his country, is deserving the warmest commendation. It is stated that the Royal Decree authorising the construction of telegraph lines in the interior of the kingdom will take effect on the 1st proximo.

TELEGRAPHY IN BELGIUM.—On the 1st January, 1864, the total length of all the telegraph wires in the possession of the Belgian Government equalled 2,647 kilometres; the number of wires to each line varying from 1 to 15. The length of wire equalled 6,238 kilometres. The number of offices open was 252. There are but five European nations which possess a greater number of offices; these are England, France, Prussia, Italy, and Austria. The Morse system is adopted in 97 offices; in the others the systems of Siemens, Lippens, and Breguet are employed. The state has supplied up to the above date a sum of 1,251,418f. for the construction of these lines, which sum has been thus apportioned:—posts and wires, 857,046f.; apparatus and accessories, 394,372f.

AUSTRALIAN TELEGRAPHS.—The telegraph is being rapidly extended in our Australian colonies. In the month of May, 1863, the following were the number of stations and the length of line open for traffic:—

	Stations.	Miles.
South Australia	30	1,500
Victoria	62	4,300
New South Wales	46	4,700
Queensland	9	240

The number of messages conveyed by these lines last year was 400,000, and the receipts on the same amounted to £80,000. A proposition is before the legislature for a grant of £160,000 to effect a junction with the great Indian line now rapidly approaching completion.

GOVERNMENT APPOINTMENTS ON THE INDIAN TELEGRAPH STAFF.—The following is the list of successful competitors at the examination held at the India Office in the last week in May for appointments in the Indian Telegraph Department:—

MAXIMUM NUMBER OF MARKS, 5,000.

	Name.	Place of Education.	Marks.
1.	Charles H. Ringwood	Trinity College, Dublin	4,209
2.	John M. Scott	" " "	3,898
3.	John C. Douglas	Birkbeck Science School	3,812
4.	George J. R. Leeson	Trinity College, Dublin	3,342
5.	Samuel W. Gerrard	" " "	3,122
6.	Jas. A. Briggs	Birkbeck Science School	2,981
7.	John Burke	Queen's College, Galway	2,632
8.	Edward S. Townsend	Trinity College, Dublin	2,606
9.	Thomas M'Kelvey	Queen's College, Galway	2,453
10.	James J. Dooley	" " "	2,433
11.	Arthur H. Curling	" " "	2,045
12.	Augustus S. Hinds	" " "	2,012

BONELLI'S TELEGRAPH.—At the annual conversazione of the Institution of Civil Engineers, held on Tuesday evening, the 31st ult., Bonelli's printing telegraph was exhibited, and the results attained are thus spoken of by the *Mechanics' Magazine*:—Two of the machines were shown in constant operation; and whatever may be the question of expense, &c., connected with this invention, its working on this occasion left little room to doubt that its action is at once very perfect and very rapid. The printing was legible in the highest degree; the entire apparatus worked without hitch or impediment at a very fast pace, and did not fail to leave a favourable impression on the minds of those who witnessed its performance.

RAILWAYS AND TELEGRAPHS.—At the University soiree, on Wednesday evening, the Silver India-Rubber and Cable Construction Company exhibited a series of samples of material for railway and telegraphic uses. one of the most ingenious models being an apparatus for giving notice of disarrangement of distant signals, which is effected by the means of electricity, and consists of a metallic spring which is so fixed that it shall be in the flame of the signal lamp. The lamp will, in four seconds, vary the temperature of the spring sufficiently to break or complete the circuit, and the change is at once communicated to the station, danger being announced by the ringing of a bell, or other suitable means. The gum, Balata, was also exhibited, and engaged the attention of the numerous scientific gentlemen present.

TELEGRAPHIC COMMUNICATION WITH AMERICA.—A company has recently been started, under the title of the International Ocean Telegraphic Company, which proposes to establish telegraph communication between Europe and America by a route which, it is contended, presents fewer difficulties than those met with in the course taken by the Atlantic Telegraph Company. Mr. W. Rowett, one of the directors of the company, attended at the Underwriters' Rooms at Liverpool recently, to explain the nature of the project. The proposed starting point of the line is Brest; thence it will be carried across the Bay of Biscay to Cape Finisterre; thence to the Azores, touching either at Terceira or Flores; and finally, skirting the southern edge of the great bank of Newfoundland, to St. Pierre, one of the Miquelon group of islands belonging to the French. The whole length of the line will be about 2,300 miles, but the longest section—that between the Azores and Newfoundland—will not be more than 800 miles in extent. The distance across the Bay of Biscay is 360 miles, and from Cape Finisterre to Azores about 780 miles. The deepest point of the route is 3,700 fathoms, and is between the Azores and the Bank. Mr. Rowett produced a specimen of the cable which it is proposed to lay down. The telegraph wire is surrounded with a coating of india-rubber, and this is enclosed within a spiral coil of hemp—a mode which Mr. Rowett maintained possessed great advantages over the outer covering of wire rope by which the Atlantic cable was surrounded. Mr. Rowett explained that the great drawback hitherto in the use of india-rubber as an insulator had been that in the process of manufacture it became mixed with foreign ingredients which were speedily acted upon by the salt water, and the insulation destroyed. Recently, however, a mode had been discovered by which the india-rubber was preserved quite pure, and this would resist the action of the water. It was proposed also to preserve the hempen covering from decay by steeping it in a mixture of which Mr. Rowett was himself the inventor, and a testimonial to the efficacy of which he produced from Admiral Elliott. The weight of the cable proposed to be used was stated to be about 3 cwt. per mile, while that employed by the Atlantic Telegraph Company was between 15 cwt. and 16 cwt. Mr. Rowett expected that a superior cable could be constructed upon this plan for about £150 a-mile, and the cost of the whole line he did not suppose would exceed £400,000. The company has obtained a treaty from the French Government authorising them to construct the line; and the money is only wanting, the capital required being £500,000, which it is proposed to raise by the issue of 25,000 shares of £20 each.

TELEGRAPH TO INDIA.—The following extract from a letter, dated Mussendom, March 25th, 1864, from a gentleman well known in telegraphic circles, will be perused with considerable interest, as it shows somewhat of the vicissitudes encountered in the laying of the Persian Gulf cable:—"Up to the present time Government have been finding us in rations, but that is too good to last long, and I believe we shall soon be on our own hook. As the Arabs were rather troublesome, threatening to do for us, &c., when the steamers were gone, and other little playful traits of character, such as never taking anything out of their reach, &c., we were all moved off the neck of land we were first encamped on, and came off to this little island, which is to be the permanent station. We were going to a place about seven miles off, but the natives are not over polite to us there I understand; so, as the clown says, here we are. The two hulks are arrived, but are not very convenient to live in, so we don't use them, and a gun-boat is moored close by. We shall have one of her Majesty's sloops up here soon to replace it. A large wooden house is being built for us in Bombay, and when it arrives I think it will be more comfortable, although since I left England I have not slept more than a dozen nights in a bed-room, and don't dislike tents at all. Two magnetics out of three have been made superintendents. I have charge of the testing these two sections of cable; in fact they were short of electricians, and I came in very handy. From the time I left the old Company I worked very hard indeed to obtain the necessary experience. Time has proved I was right in sticking to it. T—— is here. G—— is at this moment at Bushire, but I think goes on to Fao, near Bussorah. I was not able to go off to the steamer he was in, although she lay within a quarter of a mile, and therefore have not seen him. I spoke to him while they were paying out. The Government have kindly furnished us with rifles for the protection of their property; and I have my own, which shoots very well, and at present a very nice little revolver, which lays on the table of a night. This island is about 100 yards long and 60 broad, rough and stormy; no water or vegetation to speak of; in the middle of a bay about two miles or more broad. The inlet is six miles deep. The shores of the bay are composed of enormous precipitous rocks, quite barren, and which in the hot season will reflect the heat down almost perpendicular—'rather hot that.' Fish is cheap, but fresh meat scarce: we have some to-morrow, being Sunday. I have had no things washed for three months, but they have sent us a Dhobee, and I am in hopes to get some clean things in a few days. At present the climate agrees with me, and has done so very well hitherto, with exception of thirty hours, during which I had something very much like cholera—vomiting, cramps, &c. This was in Bombay, where we staid two months. From the time we left England to the time I came ashore here, I may say I never lived better in my life—almost too well for this climate. I had a very fine time of it coming overland, but I did not see F——; he had been removed to Benghazi. I liked Cairo very much; and I must not forget to mention that I was perfectly delighted with Paris. London isn't a patch on it, or at least in comparison it would be a very dirty patch. When you reply tell me all the *on dits* in the world of telegraphs, what new cables are in contemplation, who has the contract, and who are the head men, especially any Government ones, and the Australian extension line."

THE TELEGRAPH AT THE CAPE.—By the last mail we have a few particulars of the opening of the Cape of Good Hope Electric Telegraph, which extends in an unbroken line for more than six hundred miles, viz., from Cape Town to Graham's Town. It has been constructed under the engineering direction of Mr. Wollaston, by Mr. Hoeltzer, of the firm of Siemens & Co., for the Cape of Good Hope Telegraph Company; and in its substantiality and completeness is all that could have been wished for. The wire is of the best No. 6; the insulators are iron-clad, and perfect of their kind; the poles are stout, tall, and of the most substantial colonial woods; and the insulation throughout is so perfect that no more than fifteen cells of Daniell's batteries are required for working the transmission with ease the whole way from one terminus to the other. The instruments employed at all the stations are a beautiful modification of Morse's printing telegraph, in which the mechanism prints off the various messages, not by indents, but *in ink*, with a distinctness and fixedness which for present accuracy and future reference can leave nothing to be desired. On the arrival of the Saxon with the English mails, the news brought by her was telegraphed to Graham's Town and printed and published there—six hundred miles away—within fifty minutes of her anchoring in Table Bay. Profitable strokes of business have already been made by merchants speculating with frontier markets; and the Government have, equally with private individuals, experienced the vast benefits conferred by this new and great improvement. The only objection yet alleged against it has come from some extreme Eastern traders, who, naturally enough, feel apprehensive that it will for ever drown any faint hope they might have heretofore cherished of getting the seat of Government removed from Cape Town to the frontier. Stationed in Cape Town, the Governor can receive his home despatches four days earlier than he could possibly obtain them at Graham's Town; while, whatever instructions they may contain affecting frontier politics, can be flashed on by telegraph a few minutes after they have been perused in Government House. So great are the advantages derivable from this telegraph already constructed, that is is certain efforts will be made in the next session of parliament to secure its gradual extension, not only over the colony, but in a net-work of intercommunication throughout the whole of Southern Africa.

THE INDIAN TELEGRAPH.—The following remarks and correspondence appeared in *The Times* of the 9th instant:—Annexed is a communication on the Indian Telegraph question, and the present state of that portion of the line which is interrupted from the hostility of the Arabs to the Turkish Government, an evil which would have been obviated, if attention had been paid to the warnings of those who were the first to call attention to the advantages of the Euphrates route:—"Sir,—I was gratified by seeing in a late number of *The Times* an allusion to the accuracy of the predictions of Mr. Andrew regarding telegraphic communication with India, for I feel, in common with many others in the city, that England can never be in efficient telegraphic communication with India until, not only the route recommended by Mr. Andrew is carried out by the Euphrates and Persian Gulf, but until the advice of that gentlemen is followed of having the line from Constantinople to India in the hands of Englishmen. This can only be accomplished by a firm or company farming the line from Constantinople to Bagdad, which, under Turkish management, is almost, if not entirely, useless. A break has, as you state, occurred in the route from Bagdad to Constantinople, 'where the route is so wretchedly looked after, and the Turks are so slow about repairs, that it is impossible to say when it will be again in working order.' It was the wish of Mr. Andrew, who advocated so strenuously in your columns the telegraph by the Euphrates and Persian Gulf, that his company should be intrusted with the construction of the line which they projected, or that they should be allowed to farm the line for the British and Turkish Governments. He knew well enough that the Turkish Government would never manage a telegraph themselves, and that their pride would not allow

our Government to do it for them; and that the Arabs, through whose country it would pass, would not protect the line for the Turks as they would for us, whom they regard as their friends and protectors. Mr. Bidder, not long ago, in *The Times* pointed out what a mess our Government would make of the Persian Gulf cable, keeping it on their own hands, and events are confirming this opinion. Let common justice be done at last, and let those who predicted the failure of the Red Sea route and the feasibility of the Euphrates route be entrusted with the management of the plan they projected when events are proving that their advice was sound, not only as to route, but as to management. We have thrown a million of money away already by taking the wrong route—are we to throw another million away by persisting in a wrong system of management? I am, &c., A MERCHANT."

MISCELLANEA.

THE CURRENT METALS.—Compositions of zinc and copper can be made so hard that they will cut steel, and stand well for tools.

AMPERE AND THE ELECTRIC TELEGRAPH.—In the year 1820 Ampere predicted the possibility of making the deflection of the magnetic needle, by the agency of the galvanic fluid, serve the purpose of transmitting intelligence. In page 19 of his Memoir, he thus resolves the problem:—"As many magnetic needles as there are letters of the alphabet, which may be made to communicate successfully with the battery by the means of keys, which may be pressed down at pleasure, might give place to a telegraphic correspondence which would surmount all distance and would be as prompt as writing speech to transmit thought."

DAMAGE TO A CHURCH BY LIGHTNING.—During the thunderstorm at Llanellian, Denbighshire, on Friday, the 27th ult., the electric fluid entered the church at the top of two of the arches of a three-light window, in the north chancel, having burnt two holes through the lead at the apex of the arches. It knocked out some of the oak pannelling of the chancel, scattering it about the church; it then passed to the roof, scorching and blackening the gilding of the chancel arch, and passed out at the top of the gable, shattering the wall, which was about a yard thick, and raising some of the coping. It may be interesting to some of our readers to know in this instance what a strong resistance was offered to the electric fluid by the glass in the building. The lightning struck the outer wall in several places about the window and forced a passage for itself through a small hole in the leads, but at the same time divided and separated the strong stone mullioned arch at the top and some strong stone-work above the glass, without breaking a single pane of the window.

COATING IRON WITH ALUMINIUM.—Mr. Wm. Clark has invented a peculiar process for covering the surface of iron with a layer of the above metal. The surface of the iron is first cleansed; a mixture is then made of porcelain-clay, feldspar, and white lead, properly ground and incorporated; then about ten parts of this combination are added to about five pounds of calcined and powered alum-clay. This last mixture having been made into a thin paste, and poured over the surface of the metal, the latter is dried and placed in a reverberatory furnace until it presents a glazed appearance. When the iron is removed it will be found to have received a tough, adhesive, and elastic coating, which is so closely attached to the metal that, when this is bent even at right angles, no symptoms of cracking appear. This coating is also unacted on by acids and alkalies. It is supposed that during the baking process the aluminium is separated from its oxide, and forms a thin metallic stratum, intermediate between the iron and the glazed surface.

THE CHEMICAL ACTION OF SEA WATER ON METALS.—At a recent meeting of the Institute of Technology, in New York, a gentleman, well known in the American shipping interests, presented some fragments of a cast-iron propeller, which was attached to a coppered ship, which was remarkably deteriorated. To use the gentleman's own words:—"It had the consistence of graphite, and could be shaved off with a pocket-knife to a depth of $\frac{1}{4}$ of an inch from the surface." Several reasons were given for this rapid deterioration (the screw having been in the water but a few months), but the right one perhaps was not hit upon. It is well known that a piece of iron in a salt of copper will precipitate all the copper in a metallic state, and a corresponding equivalent of iron will take its place in the solution, forming thus a salt of iron. Now might not this reaction have taken place in the case of this propeller? Sea water contains soluble sulphates. The coppering of the ship was probably dissolved in the form of a sulphate, and the iron of the screw being brought into contact with this solution, the copper was precipitated and the iron was dissolved, the crust on the casting which was found to be so soft, was then composed of the oxide of iron [Fe_2O_3] probably, together with the carbon of the cast iron which was left after the iron had been dissolved; and this carbon, which is in fact graphite or black-lead, mixed with the oxide of iron, was the substance forming the crust, which could be so easily cut with the knife. If this reason should be the right one, it would be quite out of the question, practically, to use cast iron propellers on coppered ships unless they could be covered with some pigment which would preclude the possibility of contact between the iron and the salt of copper supposed to be in solution in the water.

TO BLEACH GUTTA-PERCHA.—Dissolve gutta-percha (one part) in 20 parts of hot benzole, shake the solution with one-tenth part of freshly-calcined plaster, and set aside, with occasional agitation, for two days. The clear pale brownish-yellow liquid is then decanted into another vessel containing double its bulk of alcohol fortius, when the gutta will be precipitated in the form of a brilliantly white tenacious mass.

ARTIFICIAL DIAMONDS.—An ingenious Frenchman is said to have "taken out a patent for making diamonds" at Washington. "With two bushels of charcoal he can make a diamond that will weigh a pound." Does he expect his patented process to be perused and not imitated? The "patent" is rather suspicious: the discoverer of the way to make artificial diamonds is not at all likely to take out a patent for it. The improbability of making diamonds is not so great, however, as many, even chemists, may imagine. Indeed, a French chemist is said to have already produced very small ones by fusing carbon with the aid of borax. All that would be requisite to produce diamonds of large size would be the discovery of a solvent of carbon; and the alchymists were said to have possessed such a solvent and tincture. Just as alum dissolved in water can be made to crystalline into alum baskets, so might carbon, if it could only be dissolved in some fitting menstrum, be made to crystallise into abundance of diamonds. Carbon, to be sure, is regarded as an element, while alum is a compound; but it was Davy's opinion that diamond, too, was a compound, and not mere carbon, but probably carbon in combination with some slight tinge or tincture of halogenous material in it. Now, it is a curious circumstance that the alchymical accredited solvent of carbon, or diamond-producer, was called the hyle (or halogen) of the sages, and the elixir of the stone. Doubtful, however, as the alchymical diamond-producer may have been, we are inclined to regard the Frenchman and his patent as no less apocryphal.

BLASTING BY ELECTRICITY.—The following account describes an apparatus used for blasting purposes by the engineer corps of the Philadelphia and Manayunk railroad in some operations on that line:—"The battery consisted of about 25 copper cells, 1 foot long by 18 inches deep, by 1 inch wide, open at top and bottom; these were set in a wooden frame, and separated from each other by common window glass, which was also secured in the frame; inside of each of these cells was a plate of zinc, just large enough to allow a slip of grooved wood to hold it away from the copper at the ends. Each zinc plate was connected to the copper cell next to the one in which it was placed, making thus a very large voltaic pile. From each end of this battery an insulated wire ran to the holes to be fired; that from one extremity, of course, going from the copper, and the other from a zinc plate. The acid used was sulphuric, diluted in about thirty times its quantity of water. The frame was arranged to raise and lower into a wooden trough or bath, which contained the diluted acid, by a windlass, so that the person who was engaged in connecting the main wires to those in the holes, did his work without any risk of an explosion, the battery not being lowered into the acid until he was at a safe distance. For firing the holes, two wires were taken and twisted together. At first it was thought necessary that both should be insulated, but it was soon found that if one of them was coated with gutta-percha, it was sufficient. At the end inserted into the holes these wires were separated about a quarter of an inch, and connected by a very thin piece of platinum wire; afterwards it was found that steel answered every purpose, and was much less expensive. This thin wire melted as the charge of electricity passed through it. At the commencement of the work this was inserted directly into the blasting powder, but two great disadvantages arose therefrom—first, the danger of the small wire becoming broken in tamping the hole; and, second, the difficulty of igniting the coarse blasting powder by the instantaneous spark of electricity; to avoid both of which a small paper bag, large enough to hold about a gunshot charge, was placed over the end and filled with rifle powder, the bottom being pasted, shut, and the top tied securely above the steel wire. Another difficulty then arose from the fact that in handling 'cartridges,' as they were called, the fine powder was frequently unavoidably shaken out of them. This the men who had charge of the holes soon discovered, and before inserting one, would finger the little paper bag to see if it was full, and, as their hands were generally wet, injured the powder. To avoid this, gutta-percha was dissolved in ether, and the cartridge dipped into it; and as soon as taken out of the mixture the volatile liquid evaporated, leaving a very thin coating of gutta-percha over the paper. Thus perfected, the 'cartridge' was inserted into about the centre of the charge of blasting powder in the hole, the opposite ends of the wire protruding; tamping was put in exactly as if fuse were used instead of wires. Before firing, a number of holes were connected together, by taking the protruding end of one wire of the first hole and twisting it to the end of the second, the remaining one of the second to one of the third, and so on. One of the main wires from the battery was then connected with the end of the first wire of this 'batch,' and the other to the end of the last; the battery was then immersed in the bath containing the acid, and the discharge of the whole lot was instantaneous and simultaneous. As many as twenty holes were frequently fired in one lot. The working of this arrangement was eminently successful. For three months an average of nearly a hundred holes a day were fired at each tunnel without a single accident, so far as the blasting was concerned. This system is almost identical with the one invented in France. Many of the details, such as coating the bag with gutta-percha, &c., will be indicated by local circumstances to practical minds."

THE MANIA FOR JOINT-STOCK COMPANIES.—Some national follies have a certain periodicity. You may expect to see them again about every twenty years—after an interval just long enough to allow some full-grown children, who have burnt their fingers, to forget the smart, and others to grow up who don't yet dread the fire. Just such a periodical folly is a Joint-Stock Company mania. It is founded partly on that impatience of low interest which culminates in rashness, and yet more on the gambling propensities of human nature—propensities so rife, that if you can once disguise the vulgar iniquities of the gaming-table, and deal with scrip instead of cards, there is no party within the church, and no denomination out of it, so strict in their horror of all greed and worldliness, but "feeling it their duty to exert themselves for the good of their family," will stake ten times as much with stock or shares as the worst gamester of their acquaintance ever risked at rouge-et-noir.

THE VIBRATIONS OF ATOMS.—In the world of science, while one large class of learned and intellectual men are devoting their labour to the examination of bodies and systems of matter so vast and so remote that the mind is overwhelmed in efforts to conceive the sizes and the distances, another class are engaged in the study of the structure and habits of that innumerable multitude of organized beings which are individually so small as to be wholly invisible to the naked eye; and a third class are directing their thoughts to the size, the weight, the form, and the movements of the still smaller ultimate atoms of matter, which cannot be seen even with the aid of the most powerful compound microscope. Among the most zealous of the last-named class is John Tyndal, Esq., F.R.S., Professor of Natural Philosophy at the Royal Institution. Tyndal espouses the theory that all space is filled with a subtle ether, and that light, heat, and the other imponderable forces are vibrations of this ether, each force being a vibration peculiar to itself. Where heat is produced by burning hydrogen, Tyndal says that the atom of hydrogen is drawn or propelled against the atom of oxygen with a velocity and force that produces a vibration, and that this vibration being imparted to the surrounding ether, affects our senses as heat. If the collision produces vibrations shorter and quicker, these are perceptible as light. At a recent meeting of the Royal Institution of Great Britain, H.R.H. the Prince of Wales, Vice-Patron, in the chair, Mr. Tyndal read a paper on molecular physics, from which we extract the following explanation of transparency:—"What, then, is the physical meaning of opacity and transparency as regards light and radiant heat? The luminous rays of the spectrum differ from the non-luminous ones simply in period. The sensation of light is excited by waves of ether shorter and more quickly recurrent than those which fall beyond the extreme red. But why should iodine stop the former and allow the latter to pass? The answer to this question no doubt is that the intercepted waves are those whose periods of recurrence coincide with the periods of oscillation possible to the atoms of the dissolved iodine. The elastic forces which separated these atoms are such as to compel them to vibrate in definite periods, and, when these periods synchronize with those of the etheral waves, the latter are absorbed. Briefly defined, then, transparency in liquids as well as in gases is synonymous with discord, while opacity is synonymous with accord between the periods of the waves of ether and those of the molecules of the body on which they impinge. All ordinary transparent and colourless substances owe their transparency to the discord which exists between the oscillating periods of their molecule and those of the waves of the whole visible spectrum. The general discord of the vibrating periods of the molecules of compound bodies with the light-giving waves of the spectrum may be inferred from the prevalence of the property of transparency in compounds, while their greater harmony with the extra-red periods is to be inferred from their opacity to the extra-red rays. Water illustrates this transparency and opacity in the most striking manner. It is highly transparent to the luminous rays, which demonstrates the incompetency of its molecules to oscillate in the periods which excite vision. It is as highly opaque to the extra-red undulations, which proves the synchronism of its periods with those of the longer waves."

PATENTS.

APPLICATIONS FOR LETTERS PATENT.

1345. P. Deeley, a new or improved machine for testing the strength of wire.

1386. W. Clark, improvements in electro-magnetic and magneto-electric apparatus, and their application as a stationary or locomotive driving power.—A communication.

1405. W. H. Preece, improved domestic telegraphic apparatus.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

1234. W. Reid, improvements in apparatus used for testing the insulation of electric telegraph wires or conductors.

1258. J. Webster, improvements in the manufacture of zinc.

NOTICES TO PROCEED.

1242. J. Hamilton, jun., improvements in electric telegraph posts.

PATENTS SEALED.

3116. G. T. Bousfield, improvements in the manufacture of india-rubber and gutta-percha compounds.—A communication.

PATENTS WHICH HAVE BECOME VOID.

1322. E. H. C. Monckton, improvements in obtaining and applying magnetic motive power, which invention is also applicable to other useful purposes.

PRICES CURRENT OF INSULATING MATERIAL.

GUTTA PERCHA, AS IMPORTED.

Genuine, fine and good	2/2 to 2/6	per lb.
Good re-boiled	1/6 to 1/8	„

TO CORRESPONDENTS.

Y. I.—Every attempt made at our request to make a sound joint in a core formed with virgin or unmasticated rubber resulted in failure. We shall in a future number give the tests to which an india-rubber core was subjected in one mile lengths, and the test to which the same core was subjected when joined up.

As information respecting Improvements, Extension of Lines, and Progress of New Undertakings will at all times be most acceptable, we hope that our readers will kindly render us assistance in our efforts to establish a Journal worthy in all respects of the great interest it seeks to represent, by furnishing us with brief notices of events and occurrences in connection with Telegraphy.

Communications intended for publication must be authenticated by the names and addresses of the writers; not neccessarily for insertion.

Letters relating to Advertisements are to be addressed to the Publishers. All other letters and communications to be addressed to the Editor of the *Telegraphic Journal*, 5, Suffolk-lane, Cannon-street, London, E.C.

The *Telegraphic Journal* can be had of Messrs. SMITH & Co., Strand; Messrs. DAWSON & Co., Cannon-street, E.C.; Messrs. KENT & Co., Paternoster-row, London. Messrs. HEYWOOD & Co., Manchester; at the various railway stations; and of all news-agents, &c., &c.; or it can be supplied, if preferred, direct from the Office on the following terms:—

	s.	d.
Quarterly	4	4
Half-yearly	8	8
Yearly	17	4

TO ADVERTISERS.

The *Telegraphic Journal* is the most effective medium for inventors, patentees, contractors, manufacturers of insulating materials and electrical apparatus to submit their various specialities to the consideration of secretaries and managers of telegraph or railway companies, and other persons engaged in electrical and telegraphic pursuits.

Clerks, assistants, manipulators, and instrument makers, seeking employment, &c., will find the *Telegraphic Journal* a ready means of making known their requirements.

Advertisements must be delivered to ensure insertion before SEVEN O'CLOCK on Thursday evening in each week. The charges for Advertisements are—

	£.	s.	d.
Whole page	4	4	0
Half ditto	2	10	0
Quarter ditto	1	7	6
Four lines and under (single column)	0	3	0

Single Advertisements from the country must be accompanied with stamps in payment.

THE APPOINTMENTS ON THE TELEGRAPH STAFF OF INDIA.

THERE is a great difference between having something to say, and having to say something upon a given subject. The heading to this column will indicate the matter on which we desire to say a few words; our object being not to disturb the quiet of "the yesterdays," but rather to enforce a lesson taught by experience, now that we see how *inutile* have been our previous efforts to incite young men engaged in telegraphy to a study of those branches of science by which alone they will be enabled to advance in their profession.

It will not be out of place, perhaps, if we briefly revert to the proceedings at the India Office with respect to the recent competition. According to announcement there were twenty-five appointments at the disposal of the Under-Secretary of State for India. Numerous were the applications for these offices, but the examiners were only enabled to select twelve candidates as possessing the necessary qualifications. The requirements will be found fully set forth in No. 3, page 33, of this journal; and the few applicants able to attain the specified number of marks fully corroborates an opinion long since expressed in these pages, viz., that the educational requirements were totally beyond the necessities or possible exigencies of the service, and would deter practical men from the examinations. Of the successful candidates, five were tutored at Queen's College, Galway; five at Trinity College, Dublin; and the remaining two at the Birkbeck School of Science. It is very proper that the India Board should require gentlemen of education to occupy the responsible positions in the telegraph department of the country under their direction; it is equally desirable that said officers should be competent to undertake the duties of telegraphists. This latter feature seems to have been entirely overlooked in the recent appointments; and we presume that it will be in India as is too often the case in Government offices at home, gentlemen of education will be placed in office at large salaries to see that men of intelligence do the work of the department for small wages. "It is strange, passing strange" that nearly all the successful candidates are, or have been Irish University men. We do not suppose that any undue influence has been exerted upon the examiners, as it is far more reasonable to conclude that the inducements to English University men were not considered very attractive. For this reason we are led to question the wisdom, yea, the propriety of a competitive examination on an educational basis for appointments where professional skill is of more importance than classic lore.

There are hundreds of young men engaged in telegraphy possessing a good sound English education; an acquaintance with foreign languages (a qualification which appears to have escaped attention in the recent tests); a thorough knowledge of the art in which they are engaged; and who have a very useful additional recommendation in the possession of common sense. These men would have been valuable additions to the staff of the India Telegraph Department, but they have been excluded by the utter unreasonableness of the conditions imposed. However, the appointments for the year 1864 have been made—they are of the past; but we hope that the authorities will profit by our recommendations in the future, and that we shall be able next year to chronicle the admission of practical telegraphists into the service of the India Government. We do not hesitate to affirm that there are gentlemen now deservedly occupying the most exalted positions in the India Telegraph Department (esteemed alike for their many virtues and scientific attainments) who would miserably fail to pass the set curriculum. Therefore we urge the removal of obstacles which only tend to impair the efficiency of the India telegraph staff. If ever the telegraph is to become the medium for correspondence between England and her Indian possessions, practical men must be appointed to the administration in place of collegians who have probably never seen a Morse instrument since they were ushered into existence. The qualifications for appointment on the telegraph staff of any foreign country are easily indicated when the locality of service is determined. Beyond the education which it is presumed every candidate would possess, a knowledge of languages, of meteorological phenomena, of applied chemistry, and of the art of telegraphy is all that is really required to make efficient officers. It could hardly be expected that telegraphists would be able to fulfil the exacting requirements of the India Board. They are not, as a rule, "the scions of noble sires" (in the ordinary acceptation of the terms), nor can they boast an *Alma Mater*, but there is abundant evidence to show that many of them are qualified and worthy to occupy the most responsible positions in a telegraphic establishment; and it is indeed a pity that they should be excluded from advancement in their profession, because their parents have been unable to afford them a classical education.

While pointing out the most forcible objection to the system on which appointments on the India telegraph staff have hitherto been made, we must not lose sight of the absolute necessity for special training to qualify intending candidates for the responsible duties of these offices. The superintendents and assistant-superintendents of telegraph lines in England have abundant opportunities for increasing their knowledge of the subtle agent which has been made so marvellously subservient to the purposes of mankind, and by-and-by this possession will prove the *sine qua non* to position in the telegraphic world. Electricity has been brought from the clouds to run on our messages, to direct the storm-tossed mariner to ports of safety, and for innumerable other uses in the arts and sciences; but of the nature of this mysterious fluid we are as profoundly ignorant as were our ancestors. We have ascertained a few of the circumstances under which it obeys our behests, but if we endeavour to trace its source, to analyse its substance, we are imperceptibly led into a series of hazy speculations, and after awhile feel disposed to abandon the pursuit, and derive a poor consolation for disappointment by including electrical in the category of the occult sciences. There is, therefore, abundant scope for the telegraphist to distinguish himself by observation and experiment. The phenomena constantly occurring around him has yet to be reduced to a science by patient research. The labours of Faraday, Wheatstone, and other investigators, are of a pioneering character; it yet remains for some humble experimentalist to demonstrate the laws of electricity, and none are more likely to be able to do so than those daily engaged in its applications. The scholar and the bookworm are poor competitors with practical men; and however discouraging the present prospects of honourable advancement may seem, the time is not far distant when it will be found that men who have profited by their occupation in telegraphy at home, are far better qualified to superintend the working of the telegraph in our Indian possessions than students from the various seminaries of learning.

THE ELECTRIC TELEGRAPH IN EUROPE AND AMERICA.

The historical investigations of the late Dr. Hamel into the origin of electro-telegraphy are works of great value and reliability. The doctor spared neither trouble nor expense in his efforts to establish the claims of his ingenious and illustrious countryman, the Baron Schilling, as the first contriver of an electric telegraph. At our request several valuable papers were contributed by him to telegraphic literature some two or three years ago, and at the time of his death he was engaged in collecting some additional important facts illustrative of the early progress of telegraphy in Europe, for which purpose his Imperial Majesty the Emperor of Russia had ordered copies of valuable documents, preserved at the Imperial Library, to be furnished him.

During a lengthened conversation we had with Dr. Hamel on the closing day of the International Exhibition of 1862, the contents of those documents were confidentially imparted to us. The facts disclosed in those papers had materially modified the views of the doctor with regard to the claim urged on behalf of Mr. Fothergill Cooke and Mr. Charles Wheatstone, as the gentlemen to whom the world is indebted for the realization of an electric telegraph:—

After all that had been accomplished before the month of September, 1837, in Europe by Baron Schilling, by Weber and Gauss, by Steinheil, and by Cooke and Wheatstone, it is offensive to observe that in America the painter Morse, who made on the 4th of September, 1837, a poor experiment which he considered "successful," is held out as having made an electro-magnetic telegraph before anybody in Europe.

Samuel Finley Breese Morse—born 1791, the eldest of three sons of the late Rev. Jedediah Morse, known for his geographical publications—having a taste for painting, and wishing to study this art, had for that purpose, from 1811 to 1815, been in England (at London and Bristol). At the close of 1829 he came again to Europe, and went by London and Paris to Rome and Naples, thence back to Paris, where he remained about a year to copy paintings in the Louvre. In the autumn of 1832 he returned from Havre to America.

On board the packet ship, the Sully, there was, among other passengers, Dr. Charles T. Jackson, of Boston, who had attended in Paris, besides other lectures, those of Pouillet, at the Sorbonne. I call to mind here that Pouillet the year before, in 1831, had had made his large electro-magnet, which supported the weight of more than one thousand kilogrammes.

During the voyage, which lasted from the 8th of October to the 15th of November, Dr. Jackson repeatedly directed the conversation to the subject of electricity and electro-magnetism, which gave occasion to speak about the possibility of electro-magnetic signalising or telegraphing. Dr. Jackson had with him on board a small electro-magnet, which he had bought in Paris, at Pixii fils, and also a small galvanic battery. He pointed out some means as likely to serve for the purpose mentioned by sketches, some of which I have seen in Dr. Jackson's pocket-book.

Arrived at New York, Morse endeavoured to gain his livelihood, as had been the case formerly, by painting portraits.

He being now always called professor, most persons believe that he is a professor of natural philosophy, or some other branch of natural science, but this is not the case. In 1835 he got the title of "Professor of the Literature of the Arts of Design." It was supposed that he might, in the so-called University of the city of New York, where he was then lodged, lecture on that subject, but he has never, as I know from himself, given one single lecture thereon to pupils.

As his occupation in painting portraits ever since his return from Europe in 1832 hardly produced him the means of supporting himself, he, towards the end of 1835, after Baron Schilling's exhibition of his telegraph at Bonn, undertook to try to arrange something for signalising by means of electro-magnetic action, of the possibility of which Dr. Jackson had informed him, but his trials remained without success, because he did not know what was wanted to make a powerful magnet. Two years later, in 1837, when news of the above-described doings in Europe reached America (his brother Sidney was editor of a newspaper), he, with the aid of a scientific gentleman, who knew what Professor Henry, then at Princeton, had done with regard to electro-magnets, produced something which, however, was not at all fit for practical use.

Professor Henry and Professor Bache, from America, had been in 1837 in London, and had visited Professor Wheatstone in King's College on the 11th of April, which was six weeks after Mr. Cooke had been with him. During the summer Professor Wheatstone had signified to some Americans his wish to make an application for a patent at the Patent-office in Washington.

Morse's idea, then, was not to produce on paper letters or signs representing them, but to have only ten signs for the nine digits and the zero. With these he proposed to express numbers on strips of paper. In an alphabetical vocabulary the words were all numbered. He had an eleventh sign which served to indicate that the next following signs were really to represent numbers, not words. For each of the signs mentioned he had a metal type with a certain number of Λ shaped projections. These types he introduced, one after the other, into a port-rule, by which they were moved forward. The teeth of the types were to lift a lever, by means of which the electric current was allowed to flow through the coils of an electro-magnet, causing it to attract an armature fixed to a moveable vertical lever having at its lower end a pencil, which marked on a strip of paper, passing slowly over a roller, zig-zags somewhat like the teeth of a saw.

To find out afterwards what the groups of zig-zags meant, one had to convert the digits they represented into numbers, and then look into the vocabulary for that number to learn what word was meant by it.

It was Dr. Leonard D. Gale, professor of chemistry, living in the same building as Morse, who had instructed him how to make the coils for an electro-magnet; he also procured him the necessary wire, and lent him a proper galvanic battery. Morse made him afterwards his partner, and he from 1846 held until lately a situation in the Patent-office.

When, at the end of August, 1837, amongst other news from Europe, there came in a German newspaper—the *Neue Würzburger Zeitung*—an account of the 30th of June, about Steinheil's doings at Munich, which was translated into a New York paper on the 1st of September, there was, through Morse's influence, on the following day an article printed, saying that the editors of newspapers in America, who copy such articles from European papers, do not seem to be aware that the electric telegraph—which now, as the wonder of the age, seems to have excited in Europe the attention of the scientific public—was an American discovery, and that Professor Morse had conceived it five years ago (1832) on his return from France to America. It was added "that Morse had on board the ship made no secret of the general idea, but communicated it freely to his fellow passengers of all nations, who were on the ship."

Was not this to make the Americans suppose that Baron Schilling, Weber, Gauss, Steinheil, Cooke, and Wheatstone might have learnt from Samuel Morse the art of telegraphing by electro-magnetism? As it was also mentioned that Morse had his telegraph then near his lodgings, there came on the same day several curious persons to see "the wonder of the age." One of them was Dr. Daubeny, from Oxford, in England. Another was a young gentleman, Alfred Vail, who afterwards became very useful to Morse, for he, with his brother George, made at the Speedwell Iron Works, near Morristown, in New Jersey, belonging to them, a much better instrument than that invented by Morse. Alfred Vail became, like Dr. Gale, Morse's partner.

On the day mentioned, the 2nd of September, Morse's machine would not mark anything correctly. Great efforts were employed to make it do better, and two days later, on the 4th of September, Morse at last succeeded in getting by it the numbers representing five words and the date marked. For this were wanted not less than sixty-two zig-zags, and fifteen straight lines on the slip of paper, the figure drawn on it looking somewhat like a saw-blade, with teeth here and there broken out. They represented the following numbers: 215, 36, 2, 58, 112, 04, 01837. Searching in the vocabulary for the meaning of these numbers, it was found that they were to express: "Successful experiment with telegraph, September 4, 1837."

The triumph was immediately sent for publication to the editor of the last-mentioned newspaper, and also to Professor Silliman at Newhaven, the editor of the *American Journal of Science and Arts*, and with it was sent a representation of the wonderful production.

It is to be seen on p. 168 of the 23rd volume of the said Silliman's journal; also in the London *Mechanics' Magazine* of the 10th of February, 1838.

Morse wrote at that time: "I assert to be the first proposer and inventor of electro-magnetic telegraphy—namely, on the 19th of October, 1832, on board the packet Sully, on my voyage from France to the United States. . . . All telegraphs in Europe are, without one exception, invented later than mine."

So spoke the painter Morse in America after having, with the machine which Dr. Gale had assisted him to construct on the 4th of September, 1837, obtained the described poor result. He claimed priority to everything done in Europe in the department of telegraphy. His, for practical purposes, worthless result he had obtained four weeks after the death of our Baron Schilling, who, as we know now, had, twenty-seven years before that time (1810), at Dr. Soemmerring's, at Munich, got acquainted with the first galvanic telegraph in the world, who, above a dozen years previous, had made at St. Petersburg the first electro-magnetic telegraph, which he had himself two years before exhibited to the meeting of the naturalists at Bonn, where it had so pleased that it was taken immediately to Heidelberg, and half a year afterwards from thence to England. Here a telegraph on the principle first used by Baron Schilling had, forty-one days before the 4th of September, been at work over a mile and a quarter of line in the open air, and through many miles of wire suspended in a building at the terminus of the railroad near Euston-square, in London; and Schilling had, not long before his decease, at a rope manufactory at St. Petersburg, ordered a submarine cable to be made to unite Cronstadt with the capital through the Gulf of Finland for telegraphic correspondence.

It is to be regretted that Morse, when in 1838 he, with and at the expense of a commercially-interested member of Congress, Francis O. J. Smith, came to Europe, wishing to get his apparatus patented in England and in France, was in Paris told that Baron Schilling had invented his electro-magnetic telegraph some time after his return from the frontiers of China in December, 1832, and in 1833. This erroneous statement became for Morse a welcome encouragement to confirm to himself the ill-founded priority of October, 1832, and unfortunately, in most of the works printed since that time, Baron Schilling is stated to have invented his telegraph in 1833.

We have seen what sort of a telegraph Morse, with the aid of Dr. Gale, had (in 1837) invented. It was a thing quite useless for practical purposes. Alfred Vail, with his brother, very soon after made for Morse, as I have already mentioned, a better one, and in the course of a good many years that practically very useful instrument was brought about which at present goes by the name of Morse's.

The first telegraph line in England was constructed by Mr. Cooke from London (Paddington) along the Great Western Railway to West Drayton in 1838-39. In 1840 he established the telegraph along the Blackwall Railway, and in 1841 a short line from the Queen-street station at Glasgow, through the tunnel to the engine-house at Cowlairs, on the railway to Edinburgh. In 1842-3 the line from West Drayton was continued to Slough. In 1843 two short lines in Ireland and in England were made; but in 1844 one of considerable length, all the way from London to Portsmouth, was done for Government. Some tunnels were also furnished with telegraphs.

SIGNAL LAMPS.—A new adaptation of petroleum has been made by Mr. J. Turner Hall, gas engineer to the London and North-Western Railway Company, Edge-hill Station. The great illuminating power of petroleum is generally acknowledged, but objections have been urged to its intended use owing to the accidents which have resulted from it from time to time. These casualties have, however, been attributed to the employment of the oil in its crude or partially and imperfectly prepared state, and to the lamps in which it was burned not being adapted for the purpose. Mr. Hall directed his attention to mineral oils for signal purposes and the lighting of railway stations, and after a series of experiments has succeeded in constructing a signal lamp and lantern in which petroleum may be used with perfect safety, and a brilliant and uniform light be obtained. The light is not affected by gusts of wind. It is already in successful operation in several of the stations on the London and North-Western Railway. In addition to its employment for railway signals it may also be used for lighting coal and other mines, lighthouses, and similar places. It is said that whilst the new petroleum lamp gives a large excess of illuminating power, the actual cost as compared with other oils is less by upwards of 50 per cent.

FIRING GUNPOWDER BY ELECTRICITY.

In our impression of this week will be found an account of some very important experiments with torpedoes at Chatham, and the following extract from a report presented to the Secretary of State for War, on the result of elaborate investigations and experiments made at Woolwich and Chatham by a Committee on the application of electricity from different sources to the explosion of gunpowder, will be found interesting. The report was drawn by Professor Wheatstone and Mr. Abel, chemist to the War Department:—

"1st. The explosion of a single charge of powder by means of the phosphide of copper fuze and a magneto-electric apparatus (even of the smallest size generally manufactured) is absolutely certain.

"2nd. The phosphide of copper fuze is as safe and permanent as any arrangement employed in the service for the ignition of gunpowder by the aid of friction or percussion.

"3rd. With the employment of a magneto-electric apparatus similar to that used in the Chatham experiments, and termed by Mr. Wheatstone the 'magnetic exploder,' the ignition at one time of fuzes, varying in number from two to twenty-five, is certain, and provided these fuzes are arranged in the branches of a divided circuit in the manner described. To attain this result, it is only necessary to employ a single wire, insulated by a coating of gutta-percha or india-rubber, and simple metallic connections of the apparatus and the charge with the earth.

"4th. The explosion of from twelve to twenty-five charges may be effected in the above manner at a distance of at least six hundred yards from the apparatus, with a rapidity which in its results will, in all probability, have the practical effect of a simultaneous discharge. This statement, however, only refers to charges on land.

"5th. The number of submarine charges which can be exploded with certainty at one time, by means of the magnetic exploder, is more limited; but if such charges are entirely or partially embedded in sand, mud, or other dense materials, from two to ten may be fired with certainty. If the charges are suspended in, or are immediately in contact with water, only four can be exploded at one time with certainty. By the employment of separate wires leading from the instrument to each charge, there is little doubt, however, that the results obtained with the magnetic exploder in submarine operations would be quite equal to those definitely established for the ignition of charges on land.

"6th. The only important precautions to which it is necessary to attend rigidly in order to ensure uniform success in the application of the magnet, are the proper insulation throughout of the main wire and branch wires leading from the instrument to the charges, and the thorough protection of all connections of wires from the access of moisture.

"7th. The system of firing charges by magneto-electricity thus possesses important advantages over the application of the voltaic battery to this purpose, the principal of which are, the small dimensions, weight, and cost of the magnetic exploder; that used in the experiments alluded to in this report weighed only 32 lbs. 11 ozs., and all the arrangements in connection with the instruments are so simple that any injury which they may sustain can be repaired by ordinary workmen."

The employment of electricity for the explosion of gunpowder is by no means new. Franklin and Priestley effected the explosion of gunpowder, &c., the former in 1751 and the latter in 1767; but, however, it was not till after the discovery of the voltaic pile that earnest and practical endeavours were made to apply electricity to mining and military purposes. Electricity is now employed for ascertaining the velocity of projectiles with the most satisfactory results, although when we proposed the application of electricity for such a purpose to the authorities at the War-office some twenty years ago, we were little better than laughed at.

PRACTICAL APPLICATION OF THE SPECTRUM ANALYSIS.—A beautiful practical application of the principles of the spectrum analysis has recently been made in the casting of steel. In a newly-adopted process of melting the metal, it is important to know the exact moment at which to shut down the cover of the furnace; time must be allowed for the escape of the gaseous products, which are injurious to the steel, but if that time be prolonged, an injurious effect of another kind is produced. To meet this contingency, it has been proposed to test the gases as they fly off, by means of the spectroscope, and as soon as the particular colour is observed, peculiar to the gas, which begins to escape at the moment the molten metal is in proper condition, the manufacturer will then have an infallible sign of the proper moment for closing the furnace.

THE INTERNATIONAL EXHIBITION, 1862.

(Concluded.)

Mouilleron & Vinay, Paris, M. (France, 1,438), exhibit their "*hydrostatimètre*," an instrument by which the level of water in a cistern is shown by an index placed in any required position at a distance from the cistern. This is effected by the agency of a float, which makes and breaks an electric circuit, sending positive currents at certain intervals as it rises, and negative currents at the same intervals while falling. The positive currents move the index of a step-by-step dial instrument in one direction, and the negative currents move the index in the opposite direction. The receiving apparatus is very simple; two polarized electro-magnets on Messrs. Siemens' system are so arranged that the armature of one works a ratchet-wheel in one direction, while the armature of the other works a similar ratchet-wheel on the same axis in an opposite direction; the two coils are both in one circuit, but the positive current alone moves the one armature, and the negative the other; the opposite currents simply press the motionless armatures harder against their stops—a position in which their pallets are clear of the ratchet-wheels. The ratchet is prevented from turning when the armature pallets are clear of them by a little spring friction pallet.

The transmitting apparatus is more complicated, and can hardly be described without drawings. As long as a float continues to rise it sends, at definite intervals of, say three inches, momentary positive currents; when nearly stationary it may oscillate up and down sometimes two inches lower and sometimes two inches higher than the level at which the last current was sent, without sending any current; it must fall or rise fully three inches after sending a given current before it sends any fresh current. Moreover, when it has *risen* three inches it will always send currents of opposite name to those sent after a *fall* of three inches. The problem is by no means an easy one, and appears to have been successfully solved.

Messrs. Mouilleron & Vinay received a medal for this apparatus.

A. Achard, Paris, M. (France, 1,023), exhibits in Class VIII. an electric self-acting feed, for supplying water to the boilers of stationary engines. In this invention, as in the railway brake described below, M. Achard uses the voltaic current simply to stop or hold an armature. When the armature is loose one of two pauls constantly worked from the engine turns a segmental ratchet, opening the feed-cock; but when the armature is held by the passing of a current through an electro-magnet, one paul is thrown out of gear, and the second paul into gear, working a second segmental ratchet which shuts the cock. When the cock is either fully open or fully shut, the paul in gear works in a blank space. The connections are made or broken by a float mechanically connected with a commutator outside the boiler; if the circuit fail at any point, or if the battery become too weak, the worst that can happen is that the armature would be released permanently, so that the boiler would get filled with water. Moreover, M. Achard uses a second armature, worked by the same current to ring a bell when the current is interrupted, in which case it rises and falls with an oscillating lever driven by the engine, and at each fall causes one beat of the bell. When the current is re-established this armature is held up out of the way of the oscillating lever, and the bell stops ringing. This current is interrupted by the float when the boiler is too full or too empty; the bell in either case acts as an alarum, and it also draws attention to any accident, in consequence of which the connecting wires may have been broken, or the battery become too weak. This electrical apparatus seems as certain in its action as any mechanical construction; indeed, if a failure can possibly occur in any part without being at once discovered, it would be in the float, which might possibly stick instead of following the surface of the water. This apparatus has been successfully applied in France.

M. Achard also exhibits an *electric brake* for use on railway trains. The electric current is not directly employed to produce the friction or retarding force, but the required power is obtained from the momentum of the train itself, by letting a cam on one of the axles of each carriage work a paul, which turns a second shaft round by means of a ratchet-wheel upon it. This second shaft, by winding up a chain, pulls the friction blocks against the rim of the carriage wheels until, by the stoppage of the axle, further action is prevented. Electricity only comes into play in so far as it is used—first, to determine the moment at which the paul shall begin to act; and secondly, to release the chain, and so take off the brake at the moment required.

The first object is very simply attained. The paul is on one end of a lever, rocking freely on the ratchet shaft. A prolongation of the other end of this lever is pressed by a spring against the cam on the axle. When the axle revolves this spring keeps the lever against the eccentric surface of the cam, and so rocks the lever and works the ratchet by the paul; a soft-iron armature is attached to the other end of the lever, which, as the lever rocks, slides back and forwards over the poles of an electro-magnet. The cam always pushes this slide back to its farthest limit in spite of any attraction of the magnet, even when a current is circulating round the coils; but when the cam recedes, the spring is not strong enough while the current circulates to pull the slide forward again, and it consequently remains motionless at the furthest point, so that the paul is no longer moved. A current passing round the electro-magnet thus prevents the brake from being applied, or stops its further application, but the moment the current is interrupted, the spring works one end of the lever, pulling the slide forwards, the paul takes up successive teeth of the ratchet, and the brake is applied with more and more force until the wheel is stopped.

The brake is released by means of a second system of electro-magnets. The ratchet-wheel is not rigidly fixed to the shaft on which the brake chain is wound, but connected with it by what may be called an electro-magnetic friction clutch; indeed, all M. Achard's contrivances are very properly referred by him to this leading idea, they all depend on the action of some sort of clutch worked by electricity. In this case the flat poles of a number of electro-magnets fixed to and round the shaft come against the flat faces of a disc of iron attached to the ratchet-wheel. When a current is established round these electro-magnets the disc adheres very tightly to them, and this is the case when the ratchet is used to put on the brake; but the moment the current is interrupted in this second circuit, there is no force to hold up the brake blocks, which fall back from the wheels by their own weight, turning the shaft round and unwinding the chain. Thus there are two circuits, which may be called the paul circuit and the clutch circuit. Normally the current is established through both; if the first be interrupted the brake is put on either slightly; if the interruption lasts, but a little while; or so strongly as to stop the wheel if the interruption continues. A short interruption in the second circuit again takes off the brake. The same circuits may be employed for all the carriages, or the train might be divided into short sections, each with a separate pair of circuits. The wires of the paul circuit might be so placed, that passengers in cases of great danger might cut them, and so apply the brakes.

M. Achard very properly applies the electro-magnetic force only to arrest the various armatures, instead of using it to do work. This invention has been tested in France, and favourably reported on by the Government engineer, and probably is open to as few objections as could be urged against any electric system used for the same purpose. Any accidental interruption in the paul circuit would be at once apparent, for the brakes would all be put on; but, on the other hand, an accident might occur to the second circuit without any obvious effect until the brakes were required. Finally, the writer fears that the trouble of making the connections required when the train is made up or subdivided, with the delays which would ensue in consequence of any mistake or accidental failure in the circuit, will prevent the adoption of any electrical arrangement in connection with any part of railway mechanism of such vital importance as the brake.

H. Garside, Manchester, M. (United Kingdom, 1,602), exhibits in Class VII. an *electric engraving machine*, used for engraving the cylinders of copper or brass employed in printing woven fabrics and paper-hangings. The voltaic current is used to determine, by means of electro-magnets, the slight simultaneous advance or withdrawal of any number of engraving diamond points from the varnished surface of the copper rollers to be engraved, according to the position of a corresponding metal contact point on the non-conducting surface of a prepared pattern. The pattern and cylinder to be engraved are moved mechanically in concert, and the proportion of their relative movements can be varied by mechanical adjustments. The engraving points have a slight vibrating motion given to them, which scratches off the varnish whenever brought in contact with it, and produces a series of fine zigzag lines which facilitate the retention of the pasty colouring matter used. The prepared pattern determines the moments at which this contact occurs, and the concert between the movements of the pattern and

the roller produces a similar agreement between the pattern and the figures engraved, which may clearly be made larger or smaller than the pattern in any desired proportion and in any required number. The copper, where exposed, is afterwards etched by an acid bath. This appears to be a very happy and legitimate use of electricity; the invention is of French origin.

Chevalier G. Bonelli, Turin, M. (Italy, 1,020), exhibits an *electric loom* in Class VII. This is an extremely ingenious contrivance, in which the usual Jacquard cards are replaced by an electrical arrangement worked by a pattern prepared on tinfoil with an insulating varnish.

A simple metal plate, perforated with holes, each of which is provided with a kind of piston, successively plays the part of each successive paper card in the usual arrangement. The pistons fill up every hole that is not required, but are withdrawn by electro-magnets from those holes, which require at each beat of the loom to be left open. This is effected as follows:—

A sort of metal comb, each tooth of which is the terminal of a separate insulated conducting wire, rests on the prepared pattern; whenever a tooth touches the tinfoil a circuit is completed through its conducting wire; but where a tooth rests on the varnish the circuit is broken. Each conducting wire includes in its circuit an electro-magnet. The pistons already spoken of are each composed of a small soft-iron shank and brass button-shaped head, and are all held horizontally in a frame, one opposite each electro-magnet. In one position of this frame the heads of these pistons project through the openings of the metal card or perforated plate; the diameter of each hole is a little larger than the head of the corresponding piston, each piston being exactly in the centre of its corresponding hole. In this same position all the soft-iron shanks touch the poles of the corresponding magnets, and the metal comb rests on the prepared pattern.

A certain number of the electro-magnets, corresponding to the uncovered portions of the tinfoil, are therefore active or attract the shanks, but the others exert no attraction. The frame with the pistons is now pulled forward away from the magnets; those pistons which are opposite the active magnets are held back, sliding in their frame, so that their button-heads pass behind the perforated plate, but the other pistons come forward with the frame, leaving the magnets. The perforated plate then drops a little way, and by this simple contrivance all those piston-heads which were in front of the plate are retained there, whatever pressure comes against them, for they are now excentric from the holes. The plate in this condition presents a perfect analogy with the common prepared card. A certain number of holes corresponding to the metallic parts of the pattern are vacant; the rest of the holes are blocked up, and present an unbroken surface, by which the proper hooks of the Jacquard loom are acted on during one stroke. The perforated plate is then brought back to the position first described, the prepared pattern is moved on a little step, and the same process repeated; thus, to use Mr. Le Neve Foster's words, "Each shift of the pattern, combined with the backward and forward movement of the frame carrying the pistons, produces a different series of holes in the plate, which thus becomes what may be called an universal Jacquard card, changing its face each contact in accordance with the requirements of the pattern."

When shuttles with several different colours are to be used, the pattern is subdivided into insulated portions, corresponding to the separate colours, by removing a very thin outline of foil round each; all the parts corresponding to one colour are afterwards connected. As each shuttle is thrown the battery is brought in contact with the appropriate series of insulated patches of tinfoil, producing a succession of different cards, and the pattern is not shifted forward until all the colours are exhausted. After the completion of each fresh combination on the perforated plate the battery circuit is broken by a proper contact-breaker, and the injurious spark is thus avoided, which would otherwise occur when the comb is lifted from the pattern prior to a shift.

The writer is unable to judge of the merits of the invention as applied to weaving, but the electrical arrangements are worthy of all praise. The smallest possible amount of work is thrown on the electric current, an essential condition for success with our present batteries. It is said that two cells of a Bunsen's battery will work M. Bonelli's loom.

FLEEMING JENKIN, REPORTER.

[The above valuable contribution to telegraphic literature will receive our further consideration in a future number.—ED. T. J.]

RAILWAY SIGNALS.

WE quote the following interesting communication which appeared in the *Times* of the 13th instant. Several articles have been published in our columns upon the important subject of "Railway Signals," in which the application of electricity has been strongly advocated. Our belief is that it is to electricity that we must look forward for the best and safest means of ensuring safety in railway travelling:—

To the Editor of the TIMES.

Sir,—Another of those fearful sacrifices of human life that are most improperly placed in the category of railway accidents has occurred at Egham. Distressing as is the lot of those who have to mourn the loss of friends and relatives, theirs is a comparatively merciful one when we think of those who have to suffer and those who have to witness the horrible torture of smashed limbs and other bodily injuries, which, although not sufficient to destroy life, leave the victim a miserable burden to himself and a life-long object of pity to those about him.

Without much hope of exciting the sympathies of those who in my mind are almost criminally responsible, I ask you to allow me to renew my protest against "the system" which has been the direct—the only cause of this terrible calamity, as it has been of many that have preceded it.

The company are anxious to make known the perfection of their arrangements. They say that neither the signals nor the signalmen are in fault; but, notwithstanding the perfection of their arrangements, the fact is before us—six or seven lives have been lost, and numbers of others have been mutilated and otherwise injured—injuries that in many cases will remain with them to the end of their days.

Accidents will occur, and to such as arise from unavoidable causes we must submit and take our chance. But events such as this at Egham—accidents as they are called—which take place within the limits of signals, need not, and never ought to occur.

It is most fortunate that the Prince of Wales was called to Windsor, instead of returning to town by special train, for if, as was currently reported, the unfortunate train had been stopped at Egham to allow the Prince to pass, he would have been most unjustly charged with being the proximate cause of the accident.

As I have before stated, I do not believe in perfection of arrangement as a means of securing safety, and, as far as possible, I would avoid special arrangements. I know the impossibility of timing the trains, so as to follow each other at certain distances, subject as that order is to disturbance along the road. Trains cannot be made to move like planets in their orbits, and it is this futile attempt at perfection of arrangement, taking no account of human frailty—this assuming that the regulations which have been issued will in all cases be rigidly observed, and that all will go on like clockwork—that has been the fruitful cause of many disasters in the past, and which will be found to have been the cause of the one at Egham.

In the semaphore signal rightly constructed and rightly used we have as complete a safeguard against collision, within the limits of the signals, as human ingenuity can devise. By a right construction I mean that they should be weighted, so that when untouched the arm will rise to a position at right angles with the signal-post. In this position it is known as a "stop signal." By a right use of the signal I mean that its permanent or normal position shall be to stop all coming trains; that it shall only be moved from this position in reply to the whistle of the engine-driver, and by a properly-appointed person in such a position in the station as to be able to command a view of the whole; and that, having cast his eye over the station, and finding it free from obstruction, he should then give authority to the engine-driver to pass on by depressing the signal arm. This I denominate the affirmative or positive signal.

Let us suppose that this system had been in operation over the South-Western Railway, not on the day in question alone, but as a permanent system of working the signals. The driver, on approaching Egham, would not have required to be told that before he could enter the station he must whistle, and obtain authority to pass on; this he would have done, because it was his daily practice—the habit of his life. Now let us transfer the view to the station, in all the hurry and bustle of collecting tickets. The station-master has no apprehension of a following train, because the signal is a standing protection; he knows that so long as the signal lever is untouched it cannot alter its position, and that without such an alteration no driver dare approach. He is thus enabled to concentrate his whole attention to the duty of despatching the train, and this being done, the signalman, seeing the road and station clear, would give the signal for the train to come on, holding the signal down until the train had passed into the station, and then allowing it to resume its position of a stop signal. A signal used in this way is an absolute safeguard to the station, rendering it impossible that a collision can take place within the limits of the signals on each side. I will not occupy your space by discussing the objections that have been put forth. I will only say that the assertion that the driver would run past the signal is unsupported by any human probability; he has every motive to observe the rule, none to violate it. It need not be the cause of any delay, and in the great majority of stations it would be attended with no additional cost. Surely it is a system worth trying; the signals are there, the men are there;

all that the signals would require would be to reverse their action, and there is not even the poor excuse of novelty, for the system is in operation at all junctions, and I have seen it in operation over an important and crowded line of railway in Lancashire for upwards of two years without the slightest inconvenience, and with the most satisfactory results as regards safety.

I am, Sir, your obedient servant,

Timberhurst, near Bury, June 10. THOS. WRIGLEY.

THE METAL INDIUM AND RECENT DISCOVERIES ON SPECTRUM ANALYSIS.

By PROFESSOR ROSCOE, F.R.S.*

SINCE the spring of 1862, when the speaker delivered a course of three lectures in this Institution on the Spectrum Discoveries, much has been done to increase our knowledge of Spectrum Analysis, but the whole subject is still in its infancy, and the further we advance the more we find remains to be known.

No less than four new elementary bodies have already been discovered by means of Spectrum Analysis: Cæsium and Rubidium, by Bunsen; Thallium, by Mr. Crookes; and Indium, by Reisch and Richter, of Freiberg; whilst the foundations of Solar Chemistry, laid by Kirchhoff, have been rendered more secure by the observations of Cooke, in America; Donati, in Italy; and Miller and Huggins, in England.

Cæsium and rubidium were at first only found in one or two mineral waters; they have since been shown to be widely distributed in the vegetable as well as in the mineral kingdom; they have been obtained in considerable quantities from the beet-root salt, and found in the ashes of tea and coffee, thus proving that they occur commonly in soil; whilst, quite recently, M. Pisani has found that a mineral called Pollux, occurring in Elba, contains 34 per cent. of cæsium, this metal having been mistaken for potash in the analyses which had previously been made of this substance. Thallium and its compounds have been obtained in large quantities, and their properties fully investigated by Crookes and Lamy, whilst this metal has not only been found in iron pyrites, but also in large quantities by Schrötter, in the mica of Zinnwald, and in lepidolite, from Moravia. Thallium has been shown by Boettger to occur together with cæsium and rubidium in the mineral water of Nauheim, near Frankfort; Boettger has, moreover, shown that thallium is contained in the vegetable kingdom, he has found it in the yeast of the vinous fermentation; so that thallium exists in wine; also in treacle, tobacco, and chicory. If 4 lbs. of any of these substances are employed, a sufficient quantity of thallium can be obtained, as the double platinum-chloride, to enable its presence to be easily detected. Professor Bunsen has informed the speaker that he has found a mother liquor from the Hartz, which contains so much thallium that the iodide can be obtained by direct precipitation in quantity at the rate of 10s. per lb. The speaker exhibited the spectrum of the Nauheim salt, which contains the three new elements; the spectrum of each metal is well seen by placing the mixed platino-chlorides in the electric arc.

Drs. Reich and Richter, of Freiburg, in Saxony, have lately discovered a fourth new metal in the Freiberg zinc blende. This metal has been termed Indium, from the two splendid indigo-blue lines which characterize its spectrum. Through the kindness of Professor Richter, the speaker had been placed in possession of a few grains of this new metal, the spectrum of which was exhibited by the electric lamp. In its chemical relations it resembles zinc, with which it is associated in nature; the metal can be reduced before the blowpipe to a malleable bead, when it forms a soft, ductile bead, which imparts streaks to paper on rubbing, and possesses a colour lighter than that of lead, being about the same as that of tin. The metallic bead dissolves in hydro-chloric acid with the evolution of hydrogen. The oxide of indium is formed as a yellow fusible incrustation when the metal is heated before the blowpipe on charcoal. Indium differs from zinc in the insolubility of the hydrated oxide in excess of both ammonia and caustic potash. This new element may be separated from all the known metals by precipitating its sulphide in alkaline solution, and by throwing down the hydrated oxide first with ammonia and then with caustic potash; and lastly, by precipitating the iron with dilute solution of bicarbonate of sodium. The hydrated oxide of indium then remains in solution in the pure state. Indium may be readily detected when present in its pure compounds by the deep purple tint which these impart to flame. The characteristic lines are, however, best seen when a small bead of indium salt is placed between two poles, from which an electric spark passes; the lines In α and In β fall respectively upon divisions 107·5, and 140 of the photographic scale of the spectroscope, when $Na = 50$, and $Sr\ \delta = 100{\cdot}5$. Up to the present time indium has been only found in the very smallest quantity, and hence the atomic weight of the metal and the composition of its salts have not yet been determined; in fact, the speaker was left to infer that Professor Richter sent him nearly all the compound of the metal remaining from the investigation of its properties, for the purpose of illustrating this discourse. It has only as yet been detected in the zinc blende of Freiberg; but it will, doubtless, soon be discovered in larger quantities, and its compounds more closely studied.

As regards the spectre of the well-known metals, our knowledge has been much increased by the publication of the second series of "Kirchhoff's maps of the solar spectrum and the spectra of the chemical elements" (Macmillan and Co.) In these Kirchhoff has marked the position of the bright lines of no less than thirty metals, and indicated those which, as they coincide with a dark solar line, reveal the presence of the particular metal in the sun's atmosphere. Kirchhoff's maps now embrace the whole of the visible spectrum from the line A in the extreme red to the line G in the indigo; beyond these limits the intensity of the light passing through his three prisms became too slight to enable him to draw the lines. The observations then made of coincidences of metallic with solar lines in the red and indigo portions of the spectrum confirm the conclusions drawn by Kirchhoff from his earlier observations, with the exception of the presence of potassium. This metal is not seen in the solar atmosphere; the potassium red line is not coincident with the solar line A, as it was supposed to be, nor with any other dark solar line. No metal, in addition to those previously observed, was found to possess lines coincident with solar lines, and hence the number of bodies known to be present in the sun has not been increased.

The experiments of Mr. Huggins on the spectra of the metallic elements, made with an instrument of six prisms, although not yet published in full, promise to add greatly to our knowledge on this subject: one interesting observation may be cited, viz., that the spectrum of sodium has been found to contain three pairs of lines in addition to those corresponding to the dark double line D, and that these also coincide with dark solar lines, adding to the evidence previously possessed of the existence of sodium in the sun. The audience had been already made acquainted with Dr. Miller's important researches on the photographic spectra of the metals, and with the valuable observations made by himself and Mr. Huggins on the spectra of the fixed stars. Connected with this part of the subject may be mentioned Professor Stokes's interesting investigation on the long spectrum of the electric spark, in which he shows that the vapour of certain metals, such as iron and magnesium, when heated by the passage of an electric spark, emit rays of so high a degree of refrangibility, that they are situated at a distance from the lines H, ten times as great as that of the whole visible spectrum from A to H. These highly refrangible rays only become visible at the highest temperatures, and they are not seen in the solar spectrum, although the less refrangible iron and magnesium lines are present. Hence it has been suggested that the temperature of the sun must be lower than that of the electric spark in which these lines are developed. This conclusion appears legitimate only if we know that these rays of high refrangibility are not absorbed in passing through our atmosphere; and an investigation of great interest here presents itself for those who ascend into the higher regions of the atmosphere.

The observations of Dr. Robinson upon metallic spectra have led this astronomer to doubt the validity of some of the conclusions arrived at by Kirchhoff concerning the existence of a separate and non-coincident set of lines in the spectrum of each metal. It seems, however, that Dr. Robinson employed only one prism and a low magnifying power, so that we must conclude that the observations from which he deduces the coincidence of certain lines as proving their identity in several metals, cannot impugn the results obtained by help of a larger instrument of sufficient power to resolve these apparent coincidences.

The original statement made by Bunsen and Kirchhoff concerning the spectra of the metals still remains unopposed by a single well-established fact—the statement, namely, that when a metal is heated up to a certain point, the spectrum of its incandescent vapour contains a number of fine bright lines which do not change their position with increase of temperature, and are not coincident with the lines of any other known substance. There is, however, no doubt of the fact that in the spectra of certain metals or metallic compounds new lines are developed by increase of temperature; and also that certain metals, as calcium, barium, and strontium, yield spectra of two kinds; one of these, seen at the lower temperature, and consisting of broad bands, being resolved at a higher temperature into bright lines. These bright lines do not undergo any further change on elevation of temperature, and characterize the true metallic spectrum, whilst the band-spectrum is probably produced by the incandescent vapour of a metallic compound which is decomposed at a higher temperature.

Our knowledge of the spectra of the non-metallic elements is, as yet, in a very incomplete state. To the researches of Plücker, we are especially indebted for information on this subject; he has shown that each metalloid possesses a peculiar and characteristic spectrum; hydrogen, for instance, yielding only three bright lines, all of which are coincident with dark solar lines; and nitrogen exhibiting a complicated series of bands. Plücker has lately come to the conclusion that many non-metallic elementary bodies, and among them sulphur and nitrogen, exhibit two distinctly different spectra when the temperature is altered, in this respect resembling the metals of the alkaline earths. This difference Plücker ascribes to the existence of these elements in two allotropic conditions.

A singular relation with regard to what have been termed the carbon lines was observed by the speaker. It has been stated that all the various forms of carbon compounds, when in a state of incandescent gas, yield identical spectra. This proves not to be the case; the spectrum obtained from the flame of olefiant gas is different from that obtained by the electric discharge through a vacuum of the same gas; whilst the spark, passing

---

* Read before the Royal Institution, Friday evening, May 6th, 1864.

through a cyanogen vacuum produces a spectrum identical with that of the olefiant gas-flame, and through the carbonic oxide vacuum a spectrum coincident with that of the spark through olefiant gas vacuum.

As an illustration of the application of abstract scientific principles to useful practical purposes, the speaker stated that he had lately applied spectrum analysis to the manufacture of steel by the Bessemer process. One of the great drawbacks to the successful practical working of Mr. Bessemer's beautiful process for converting cast-iron directly into steel, has been the difficulty of determining the exact point at which the blast of air passing through the molten metal is to be stopped. The conversion of five tons of cast-iron into cast-steel usually occupies from fifteen to twenty minutes, according to the varying conditions of weather, quality of the iron, strength of the blast, &c. If the blast be continued for ten seconds after the proper point has been attained, or if it be discontinued ten seconds before that point is reached, the charge becomes either so viscid that it cannot be poured from the converting vessel into the moulds, or it contains so much carbon as to crumble under the hammer. Up to the present time, the manufacturer has judged of the condition of the metal by the general appearance of the flame which issues from the mouth of the converting vessel. Long experience enables the workman thus to detect, with more or less exactitude, the point at which the blast must be cut off. It appeared to the speaker that an examination of the spectrum of this flame might render it possible to determine this point with scientific accuracy, and that thus an insight might be gained into the somewhat complicated chemical changes which occur in this conversion of cast-iron into steel. At the request of Messrs. John Brown & Co., of the Atlas Works, Sheffield, the speaker investigated the subject, and succeeded in obtaining very satisfactory and interesting results. The instrument employed was an ordinary Steinheil's spectroscope, furnished with photographic scale and lamp, and provided with a convenient arrangement for directing the tube carrying the slit towards any wished-for part of the flame, and for clamping the whole instrument in the required position. By help of such an arrangement the spectrum of the flame can be most readily observed, and the changes which periodically occur can be most accurately noted.

The light which is given off by the flame in this process is most intense; indeed, a more magnificent example of combustion in oxygen cannot be imagined—and a cursory examination of the flame spectrum in its various phases reveals complicated masses of dark absorption bands and bright lines showing that a variety of substances are present in the flame in the state of incandescent gas. By a simultaneous comparison of these lines in the flame-spectrum with the well-known spectra of certain elementary bodies, the speaker has succeeded in detecting the presence of the following substances in the Bessemer flame:—Sodium, potassium, lithium, iron, carbon, phosphorus, hydrogen, and nitrogen.

A further investigation with an instrument of higher dispersive and magnifying powers than that employed, will doubtless add to the above list; and an accurate and prolonged study of this spectrum will probably yield very important information respecting the nature of the reactions occurring within the vessel. Already the investigation is so far advanced that the point in the condition of the metal at which it has been found necessary to stop the blast can be ascertained with precision; and thus, by the application of the principles of spectrum analysis, that which previously depended on the quickness of vision of a skilled eye has become a matter of exact scientific observation.

Another interesting practical application of our knowledge concerning the properties of the kind of light which certain bodies emit when heated, is the employment of the light evolved by burning magnesium wire for photographic purposes. The spectrum of this light is exceedingly rich in violet and ultra-violet rays, due partly to the incandescent vapour of magnesium, and partly to the intensely-heated magnesia formed by the combustion. Professor Bunsen and the speaker in 1859 determined the chemically active power possessed by this light, and compared it with that of the sun; and they suggested the application of this light for the purpose of photography. They showed that a burning surface of magnesium wire, which, seen from a point at the sea's level, has an apparent magnitude equal to that of the sun, effects on that point the same chemical action as the sun would do if shining from a cloudless sky at a height of 9 deg. 53m. above the horizon. On comparing the *visible* brightness of these two sources of light, it was found that the brightness of the sun's disc, as measured by the eye, is 524·7 times as great as that of burning magnesium wire when the sun's zenith distance is 67 deg. 22m.; whilst at the same zenith distance the sun's *chemical* brightness is only 36·6 times as great. Hence the value of this light as a source of the chemically active rays for photographic purposes becomes at once apparent.

Professor Bunsen and the speaker state in the memoir above referred to, that "the steady and equable light evolved by magnesium wire, burning in the air, and the immense chemical action thus produced, render this source of light valuable as a simple means of obtaining a given amount of chemical illumination, and that the combustion of this metal constitutes so definite and simple a source of light for the purpose of photo-chemical measurement, that the wide distribution of magnesium becomes desirable. The application of this metal as a source of light may even become of technical importance. A burning magnesium wire of the thickness of 0·297 millimetre, evolves, according to the measurement we have made, as much light as 74 stearine candles of which five would go to the pound. If this light lasted one minute, 0·987 metre of wire, weighing 0·120 grammes, would be burnt. In order to produce a light equal to 74 candles burning for ten hours, whereby about 20 lbs. of stearine is consumed, 72·2 grammes (2½ oz.) of magnesium would be required. The magnesium wire can be easily prepared by forcing out the metal from a heated steel press having a fine opening at bottom; this wire might be rolled up in coils on a spindle, which could be made to revolve by clockwork, and thus the end of the wire, guided by passing through a groove or between rollers, could be continually pushed forward into a gas or spirit lamp flame in which it would burn."

It afforded the speaker great pleasure to state that the foregoing suggestion had now been actually carried out. Mr. Edward Sonstadt has succeeded in preparing magnesium on the large scale, and great credit is due to this gentleman for the able manner in which he has brought the difficult subject of the metallurgy of magnesium to its present very satisfactory position.

Some fine specimens of crude and distilled magnesium weighing 3 lbs. were exhibited as manufactured by Mr. Sonstadt's process, by Messrs. Mellor & Co., of Manchester.

The wire is now to be had at the comparatively low rate of 3d. per foot;* and half-an-inch of the wire evolves, on burning, light enough to transfer a positive image to a dry collodion plate; whilst by the combustion of 10 grains a perfect photographic portrait may be taken, so that the speaker believed that for photographic purposes alone the magnesium light will prove most important. The photo-chemical power of the light was illustrated by taking a portrait during the discourse. In doing this the speaker was aided by Mr. Brothers, photographer, of Manchester, who was the first to use the light for portraiture.

ON THE PATENT LAWS.

(*Concluded.*)

Mr. W. BRIDGES ADAMS writes:—

A strong effort is now making, by a small but energetic body of persons, against the continuance of the patent laws, on the ground that they are injurious to the general interests of the community. Could they make out their case, it would be quite right that the laws should be abolished, for the interests of a small body of persons, such as inventors, must give way to the general interest. It has been long conceded that individual property in matter is a general advantage, much more so than possessing matter in common. It could not be tolerated that large estates should be the property of individual owners save by the conviction that this ownership produces on the whole a larger usufruct for the general benefit. Nor would the owners of these estates portion them out in farms of greater or less size save from the conviction that by individual skill and possession they reap a larger rent. Were it not so, the land would be all in common and unenclosed. Every man in the community seeks as far as he can to obtain a monopoly of all the things he desires, and so the landlord has a monopoly of his estate, and in the farmer of his farm, and in the miner of his mine, and in the mill-owner of his mill, and so on through all the various conditions of propertied life. But that which gives the highest value to matter is mental ideality. Without this we should be mere clods—of the earth, earthy. Our talk would be of beeves, and we should scratch the earth's surface skin deep, as most half savages do, to get a scanty crop of grain and roots. To make mental ideality fructify and constitute public utility, we must do by it as we do by matter, give it individual ownership and enclosures, not mock, but real. For though it is quite true that even as unenclosed land will produce a wild crop, so will unenclosed mentality, but the value will be in the same proportion that rye grass bears to wheat of the highest standard. Men of mark and cultivation, and consecutive mental industry, will not sow that others may reap the harvest. They will either keep their ideas concealed, or they will set their investigating faculties at work to ascertain why, if the ideas of the brain are to be made common property, matter also should not fall into the same category. It is quite clear that the inventor has no inherent right in his invention beyond keeping it a secret, and that he can only turn it to his own profitable account by the agency of the community, who are to use it directly or indirectly, for if there were no community his invention would be valueless. His advantage and that of the public must advance with equal steps, and it is for the public who grant the right to consider whether, upon the whole, it is not more for their interest to protect and help these inventors than to thwart and starve them. Inventors proper are not numerous; even the patentee list—and far be it from us to assert that all patentees are inventors—the patentee list falls far short of the booksellers' list of large and small poets and rhymesters inclusive. They rank with, and are a part of, the original-minded men who have the perception of truth and beauty and analogy in all things—thought, language, sound, form, colour, and structure. In virtue of their instinctive and not mere imitative properties, they are men of genius who direct their fellows into new tracts, and constitute the great distinction between the English nation and the Chinese. Poets, bookwriters, painters, sculptors, musicians, chemists, and constructors, all fall into the same category, and are all represented by matter, and the nation may, if it chooses, deprive them of the right of property in their own creations. The

* From Messrs. Johnson & Matthey, of Hatton Garden.

poet and bookwriter gather their royalties from the manufacturers of books or may print themselves exclusively. The painters and sculptors gather royalties from the multiplication of their works in casts and engravings. Musicians gather royalties on the sale of their measured notes represented in print, and there is no more justice or policy in shutting out the constructor and chemist from their royalties or their originalities, than there would be in throwing open the writings of Kingsley, Dickens, or Tennyson, to the voluntary contributions of Paternoster-row. We do not wish to use the *argumentum ad hominem*, but, nevertheless, we cannot accept the arguments of interested men against patent laws, which act as a curb on their desires to possess a capitalist monopoly. They profess a desire to see inventors rewarded without patents, but they do not tell us how this is to be done. Is it to be by Parliamentary grant? How then is the inventor to be defined if there is no record of his invention, no making it patent? Is he to enter into a squabbling and canvassing contest with loud-tongued, unscrupulous pirates, and canvas the members for their votes? This would be to make it a matter of politics, like a contested election, in which the retiring student would have no chance against the brazen and unscrupulous man of action. But, say the opponents of patents, there is an injustice in giving an exclusive privilege to a man to-day for that which another man might invent to-morrow, or next day, or a month after. Similarly so might it be said, that it is an injustice for a duke to possess an estate which might next day or week have become the property of an earl had he not been forestalled; or that it is an injustice for England to possess New Holland, which might otherwise have become a possession of France. We cannot see the injustice that a man who is up and doing should take possession of that which had before his time no owner, and is in fact a creation, or procreation of his own. There has been much talk about the absurdity of many patents, and how few of them are of any value, while they are obstructive to inventors, and that it is necessary to sift them by a preliminary examination? Do people really understand what this means—that a man's secret—his invention—shall be canvassed and discussed, and the patent given or withheld at the option of the examiners? Is it possible to remove from a sanguine man's mind the idea that some wrong motive has been at work, that nepotism has refused to him what will be granted to some friend of an examiner. Warn the man, if it be needful, but give him his patent if he persists, and after he has specified, put it on trial, in full court, and expunge it from the records for sufficient reason. The man will then have justice, and the patent lists will not be damaged. Assuming that patents are useful to the public, as tending to make men work earnestly and consecutively at new things, it becomes necessary to ask what should be a good and fitting subject for a patent, and what not. What is novelty? It is an old saying that "there is nothing new under the sun." As regards the public, everything is new that has not been in use for a generation; and the fact that a thing has been recorded without being used should not invalidate an inventor from turning it into use under the protection of a patent. If a thing has disappeared from public use for the space of thirty years, it would be a positive advantage to the public that an inventor should have a patent—a mental enclosure—to induce him to foster it and give it a new birth. Still the outcry is of "monopoly," the cuckoo cry of free trade, as though there were any opponents of monopoly so strenuous as the inventive men, as though the whole world would not be a monopoly save for these beaters down of the old ways. The true monopolist is the capitalist, and man in possession by virtue of his position. He may allege that he is open to competition, but this openness is only in the sense that the doors of the London tavern are open to all customers who have money in their purses. In competition the race is to the rich, and the poor competitor is hustled off the ground. Let an inventor without a patent bring to bear any improved article in large demand, he will infallibly be competed with, and displaced by, the larger capitalist, whose small profit on a large return will leave no profit at all to the man of small return, who, perchance, has expended all his means in perfecting the new article. But if he be protected by a patent, the inventor can hold his own till he himself become a capitalist too strong to be damaged, unless ruined by processes on the part of the capitalist, owing to the defective state of the law. It is the inventor who breaks down the would-be monopolies of capital; and other competing inventors also, in their turn, break down the monopoly of the first inventor. They do not debar the capitalist from his right to compete in his accustomed fashion, but only to compete in the inventors' brains and new uses. Many prominent persons there are whose opposition to patentees is grounded on a case of defeated piracy, or in a desire to prevent all others but themselves from rising to eminence. This patent record and protection is the only fulcrum by which the inventive non-capitalist can lift himself to a level with the capitalist manufacturer, and disturb the stagnation which would else prevail. The competition of manufacturers is for quantity, not for quality. The inventors generally cheapen as well as improve—they substitute machines for human drudges, with far better results in quality. To attempt to reward inventors by grants is the merest moonshine. The reward would never get to the true inventors, but would be intercepted by the jobber; for the student qualities that constitute an inventor are not the qualities that canvass the attention of Governments or Government authorities. Even were it not so, how is the money value of an invention to be estimated? Only by its pecuniary success, giving an exclusive right to the owner, for a longer or shorter period, to manufacture or use himself, or to licence others so to do. But there is another argument used by the manufacturers which has a groundwork of reason; they allege that they can compete, on favourable terms, with all the world in manufactures, but that a patent in England, when there are no patents on the Continent for the same thing, puts them at a disadvantage with the foreigner. For example, the rise in price, and probably in profit, on English iron, enables Belgian iron masters to compete in the market of the world, subject always to the condition that the English iron masters can underbid them if very troublesome. But if upon any article, rails, or others, there be a patent right in England and none in Belgium, they must remain at a disadvantage. What does this amount to? That they seek to monopolise the iron manufacture, and, therefore, they should establish themselves in Belgium, or they should take the Continental patents for the invention, and so guard themselves. Anyhow, we do not see why their interest should be studied in preference to that of the inventor if they do not choose to help themselves by helping him. "But the patent law," say they, in a sudden accession of care for the interests of the inventor, "is a mockery, a delusion, and a snare to the inventor; so let us abolish the law." We may paraphrase it thus:—"The law of freehold in land is a mockery, a delusion, and a snare for the landholder, for it exposes him to be ruined in Chancery; therefore, let us abolish the law of freehold." I think that it is far better in the interest of the public to amend the law, and I would do it after the following fashion:—1. I would define novelty to consist in the fact that the thing patented had not been in use in England for a term of thirty years previous to the application. 2. I would have an applicant warned by the proper authorities that his application was for an invalid thing, but give him time nevertheless to record and specify, on the ground that no examiners should be entrusted with a power to refuse an application for reasons which might be insufficient or possibly interested. But as soon as the specifications were lodged, it should be put on trial in open court, at the cost of the community, and erased from the records for good and sufficient reasons, removing a stumbling block, or expunging any part of it required. 3. That all new and original things in a patent for any specific invention should convey a right to their use in every manner, *i.e.*, a new thing specified in an improvement for one machine should be applicable to every variety of machine, and an inventor should not be obliged to take two several patents for a gun and shot, or for wheels and rails. 4. That the patent should be renewable as a matter of course if the inventor, from no fault of his own, but from difficulty of introducing it, had failed to realise a certain rate of profit to be determined on. 5. That all trials as to patent validity, constituting it a property or otherwise, should be before an especial patent court, whose favourable verdict should be essential to patentee litigants before going into a court of law to obtain damages. We do not think that the tendency of disinterested public opinion is against patents, but the contrary. The chief opponents are those who wish capital to be individual property and brains common stock. The patent is the trade mark of the inventor; and if that be taken from him, we trust that the trade marks of the manufacturers will be thrown open at the same time, for these trade marks, earned by long and hard work, are as much a monopoly in the market as the patent earned by the long and hard work of the inventor, for if one trade mark may compete with another, so also may one patent compete with another. We should like to know of what kind is the reward proposed by Mr. Hawes for inventors? On him has descended the mantle of his relative, the late Mr. Brunel, and it is upon the records of the Committee of the House of Commons that Mr. Brunel's idea was that all inventions were made by workmen, and that a good master would reward them well,—one pound sterling for an ordinary invention, and five pounds sterling for something extra good. Mr. Hawes's definition of the distinction between copyright and patent right is hardly logical. What does copyright mean but the exclusive right to manufacture a particular book, and what does the patent right mean but the exclusive right to manufacture something else—the book originating in one brain and the something else in another. Invention is essentially forethought—a grapple with the future. Contrivance is afterthought—a patch upon the present, but the contrivance coming into an existing market is always better paid than the invention, and the inventor is frequently sneered at as being before his time. But for all that, it is the inventor who changes the face of the universe for the better, and lessens the drudgery of humanity, and adds to its resources and pleasures, while the capitalist and contriver reap the profits. It will be an evil day for the world if ever the counsels of Achitophel shall prevail to the starvation of originators. Nor do we see the justice of compelling the inventor to licence his rivals who may be interested in damaging his plans by bad workmanship, and over whose dealings he can have no satisfactory control. Some years back there was a humourous illustration of this practice. An umbrella-maker advertised "the best silk umbrellas from 7s. 6d. upwards," and then added, with a vindictive animus against Sangster, from whom he had been compelled to take a licence, "N.B. A parcel of ugly alpacas on hand." Meanwhile the clear brain of the Lord Chancellor is getting in the thin end of the wedge, and his efforts will, doubtless, culminate in an Inventors' Court of Equity, for the legalisation of mental title deeds, at the cost of the Accumulated Patent Fund.

Mr. EDMUND HUNT writes:—

Referring to the discussion on the 20th inst., I think it is a pity that, in order to avoid confusion, separate occasions were not chosen for dealing with the two great sections of the subject:—The question whether legal protection of inventions should be retained or abolished? and the question

whether the existing patent laws could be improved, and how? As to the first, I would ask whether protection should be retained from principle or from expediency? I think the only sound arguments in its favour are those grounded on expediency; and if so, what may be expedient now may not be so ten years hence. Ten years ago I was enthusiastically in favour of patents; but unusually good opportunities for studying the subject, and for general observation thereon, have brought me gradually round to the firm conviction that the time is not far off when it will be better, both for the inventor and for the public, for patents to be abolished. But I must by no means be ranked with certain recent agitators against the patent laws, for I believe the very injudicious and faulty character of their arguments will have the practical effect rather of retarding than of hastening the abolition of patents. I do not, however, think that patents will be abolished at present, and it would therefore be a waste of time to enter very fully into this branch of the subject. And although I hold opinions against the future expediency of patents, I do not suppose I am, on that account, the less likely to have sound views as to the practical defects of the existing laws and their remedy. As to definitions, which, as was truly observed, are of great importance in a discussion of this kind, I would call that a non-patentable discovery in which we find out how two things have been combined, or have acted on each other; and that a patentable *invention* in which we combine or make to act together two things which, as far as we are aware, never before were so combined or made to act. In the strict sense of the terms, the human mind is utterly incapable of creating or originating even ideas. It receives its materials from without, and simply re-arranges them, and that not after any new plan, but in more or less close imitation of arrangements it has seen. A great many frivolous remarks are often made in discussions of this kind about patents for frivolous things. If the things referred to are really frivolous, how can the public possibly suffer from their being patented, seeing that no one is bound to buy or use a thing because it is patented, and that no one will buy or use a thing that is, in his opinion, frivolous? The patentee is the sole loser, namely, of his time and trouble, and of the cost of his patent; but it is useless to tell him it is frivolous—he knows better. Obviously the moment anything becomes useful and is wanted, it ceases to be frivolous. All plans for dealing with the merit or value of inventions, in anticipation of their use, are utterly impracticable. I also consider it impossible for a board of examiners to deal satisfactorily, in all cases, with the question of novelty. The American system has not worked satisfactorily. But it is certainly not right that when an inventor pays Government for documents ostensibly giving him a certain protection, his payment should be received as for a *bona fide* protection, when there exists in the Government office the means of knowing that, in many cases, it is worthless, from protection having been previously granted for the same thing. It is like obtaining money under false pretences. The remedy is, in my opinion, to employ a staff of examiners and searchers, who, as soon as possible after the receipt of every application for a patent, with a description of the invention, shall compare the same with existing patents and other records, and shall draw up a report, stating in what cases the invention appears to have been in any way anticipated or even approached. This report should be delivered to the applicant, and it should be left to himself whether to complete his patent or not; whilst, to prevent parties from imposing on the public by completing their patents, in the case of the inventions being old, and in face of the reports to that effect, such reports should be accessible to the public, and be printed along with the specifications. Surely a patentee is entitled to receive for his freely-paid fees a return such as the information contained in the report would be. In this plan I thus propose to adopt the good features of the American system, without the faulty feature of the arbitrary power of refusing a patent. But I believe that what would be found in practice to be the most advantageous alteration the present Patent Laws are capable of, would be to enact that the public use of an invention by the inventor or in imitation of him, for a period previous to his applying for his patent, should not invalidate such patent. In our own Indian Patent Laws twelve months are allowed, and in the American laws two years; and in America this provision has proved itself to be most valuable. At present in this country patents are taken out for a great number of things which prove impracticable or useless, but which, if the suggested alteration were made, would have been tried before it became necessary to apply for a patent. On the other hand, a great number of valuable improvements are continually being made without patents being thought of at the time, and afterwards when practical and recognised success suggests a patent, the inventor finds his publication of the improvement has debarred him from getting a valid one. With the alteration suggested, patents for such really valuable improvements would take the place in the lists of the class of useless ones previously referred to. The difficulty about compulsory licences arises from inherent defects inseparable from any patent system. Although, in consequence of existing prevalent ideas, but which have been fictitiously induced, a patent holds out a certain amount of encouragement to an inventor, it is still certain that it is often obstructive to improvement. Mr. Webster's challenge to cite cases of obstruction is ingenious; but numerous examples could easily be detailed; in fact, the larger portion of patent trials for infringement are due to it. The encouragement patents afford is measured out in doses not to be exceeded; and progress must take a stride only once every fourteen years! But it is said compulsory licences would obviate the obstructiveness of patents. They might, and have other advantages also, if a satisfactory system could be suggested. Has a practical system of compulsory licences ever been suggested? I think not. It would obviously not do for patentees to fix their licence rates without some check to prevent their being so high as to be prohibitory. I don't think the machinery of arbitration at all suitable; and any patentee determined to be obstructive, and having the means, could easily delay a settlement, or make it the starting point of interminable litigation. A plan which would make it against the patentee's interest to charge too high a rate would be most likely to work well; but no way of embodying that feature has occurred to me but one, which I fear is too complicated, and involves too much change in the general system of patents. I would reduce the fees payable on obtaining a patent to those barely sufficient to cover office expenses, but patentees should pay a tax on realised profits, to be fixed in amount in the following manner:—Every patentee should advertise his rate for granting licenses, and at regular periods give in returns of the number of machines sold, or equivalent particulars, and of licenses granted, and he should be taxed on such returns at rates corresponding to his own licence rates; so that the higher he fixed his rate the larger would be his tax. The preliminary fees might also be deemed to be a payment in advance to account of the periodical taxes. The following enactment is loudly called for, namely, that every patentee shall affix the number and date of his patent on every article made under it; and a penalty shall be exacted from any one using the designation "Patent" without having a patent. It is very remarkable that whilst in the case of designs such an enactment is in force, the laws of patents, of so much greater importance, are without it.

Mr. HARRY CHESTER writes:—

On Wednesday last I was, and on Wednesday next I shall be, unable to attend the meeting for discussing the Patent Laws. *Tempora mutantur nos et mutamur in illis.* I remember that, in 1864, the opinions, or (should I say?) the feelings, of those who attended our meetings were commonly in favour of patents, and even of our present Patent Laws. Now everyone gives up the latter as mischievous, and many are altogether opposed to the former. Regarding the patent system as one of the worst of lotteries, wherein the blanks bear a higher proportion than usual to the prizes, I think that the Society, while it promotes improvements of the system, so as to minimize its evils, should set itself to consider whether any substitute can be invented for the encouragement of inventors, or rather, I should say, for the honouring of great inventors. It seems to me that, while we have orders of merit for the reward or acknowledgment of great statesmen, diplomatists, lawyers, and military and naval heroes, we want an order for the acknowledgment of the merit of great heroes of invention in Arts, Manufactures, and Commerce. I do not pretend to indicate in detail the conditions under which such an "Order of Inventors" might be useful. I think the Society might appoint a committee to consider the subject; and I will only add here that it seems to me that it would be essential, first, that no award should be made in respect of any invention which had not been in use for a sufficient number of years to allow public opinion to be ripened in respect of it; and, secondly, that in special cases of great merit or need, a pecuniary recompense from public funds should accompany the grant of the order to the inventor, or to his heirs, or to both himself and his heirs.

THE RICHARD ROBERTS MEMORIAL.

The following circular has been lately issued:—

The Society of Arts, John-street, Adelphi, W.C.

It having been proposed by numerous persons conversant with the career of the late Mr. Richard Roberts that there should be some substantial and permanent record of the eminent services he has rendered to this country, and to the world at large, by his useful inventions, a public meeting was held at the house of the Society of Arts, on the 27th ult., when the following resolutions were unanimously passed:—

"That this meeting is of opinion that the eminent services which Mr. Richard Roberts has rendered to the manufacturing industry of this country, and to the world at large, by his useful inventions, demand some substantial and permanent record; and that the most appropriate tribute to his memory would be, in the first instance, to provide for the independence of his only daughter.

"That a fund be raised by public subscription, and that a committee be appointed to carry out the foregoing resolution.

"That this meeting, feeling that there are comparatively few beyond the circle of his scientific acquaintance who know how greatly Mr. Roberts has contributed to the wealth of the country, and to the material progress of the world, deem it expedient to issue an abstract of his memoirs, recounting the most conspicuous of his inventions."

Subscriptions will be received by Messrs. Coutts & Co., Strand, W.C.; Messrs. Hallett, Ommanney & Co., 14, Great George-street, Westminster, S.W.; Messrs. Heywood, Bros., of Manchester; and by the hon. secretaries.

P. LE NEVE FOSTER, J. WILLIAMS JONES, } Hon. Secs.

The following noblemen and gentlemen form the committee:—His Grace the Duke of Sutherland; the Earl of Caithness; the Right Hon. Lord Stanley, M.P.; Lord Alfred Churchill, M.P.; Admiral Sir Edward Belcher,

K.B.; W. Bridges Adams, Esq., C.E.; John Anderson, Esq., Royal Arsenal, Woolwich; J. G. Appold, Esq., F.R.S.; T. Bazley, Esq., M.P.; Byramjee Cama, Esq.; David Chadwick, Esq.; D. K. Clark, Esq., C.E.; Zerah Colburn, Esq., C.E.; W. Fairbairn, Esq., LL.D., F.R.S.; Lieut.-Colonel French; Oliver Heywood, Esq., Manchester; Peter Graham, Esq.; S. C. Homersham, Esq., C.E.; A. Hutton, Esq., Liverpool; S B. Lamb, Esq; W. H. LeFeuvre, Esq., C.E., F.G.S.; Henry Maudslay, Esq.; J. E. McConnell, Esq., C.E.; Lieut.-Colonel Munn, Newchurch, Lancashire; Jas. R. Napier, Esq., Glasgow; Dadabhai Navroji, Esq.; J. Pender, Esq., M.P.; John Penn, Esq.; Mark Philips, Esq.; Capt. Jasper Selwyn, R.N.; W. Smith, Esq., C.E; Samuel Thornton, Esq., J.P., Birmingham; John Trotman, Esq.; Thomas Webster, Esq., F.R.S.; Dr. James Whitehead, Manchester; Bennet Woodcroft, Esq., F.R.S.; James Wilson, Esq., Manchester.

Richard Roberts was born in Denbighshire, April 22nd, 1789, and died in London, March 11th, 1864, in his 75th year. In this long life his extraordinary inventive powers, and his skill as a practical engineer, contributed, to an incalculable extent, to the wealth not only of England, but of the whole civilized world. He first came to London in 1814, and was employed for a time in the factory of the Messrs. Maudslay, then the highest school of mechanical engineering in the kingdom. Three years later Mr. Roberts, then in business for himself in Manchester, made the first planing machine for iron, and which is still preserved in the Museum of Patents, South Kensington. His slotting machine and wheel cutting engine soon followed, and these, with his improvements in the slide lathe, may be regarded as among the most important of the aids which invention has given to construction. This series of inventions introduced a precision, celerity, and cheapness into the production of mechanism never before known, the results extending not only to the largest engines of ocean steamships, and to the endless machinery of the great factories of Lancashire, but down to the railway ticket press and the sewing machine. His talents and great practical abilities soon led to Mr. Roberts being invited to a partnership with the late Thomas Sharp, Esq., with whom Mr. Roberts established the Atlas Works, still ranking among the largest and most productive mechanical engineering factories in the kingdom. Here, in 1825, in consequence of the formidable strikes among the hand-mule spinners, he was led to the invention of perhaps the most ingenious, as it has been one of the most valuable, machines in the whole range of textile manufactures. This is the self-acting spinning mule, requiring only the attention of a child in the production of a thousand threads of an evenness and fineness unattainable by either the hand-mule or the throstle. Many millions of spindles are now worked upon Mr. Roberts's principle, not only in Lancashire, but in every civilized country. Shortly after the opening of the Liverpool and Manchester Railway, Mr. Roberts directed his attention to the improvement of the locomotive engine, and many of his original refinements in its structure and workmanship may still be traced in the railway engines of the present day; and of these, it may be added, nearly 1,500 have been constructed at the works where Mr. Roberts completed his first locomotive thirty years ago. One of his most valuable improvements introduced into the manufacture of these engines, and originally applied by him in 1825 in the construction of his spinning-mules, was the application of standard templates to the forms and dimensions of every part. This system permitted of the exact repetition of every portion of a machine to an endless extent, and it is that whereby the Enfield rifle is now made under a perfect division of labour; so that any one of a hundred thousand like parts fits exactly any one of an equal number of corresponding parts. Mr. Roberts received most tempting offers from the French and Russian governments to establish himself abroad, but declined, although he found time to design and put in operation Messrs. Koechlin's large engineering factory at Mulhouse.

During a long and active career he applied himself to the invention and introduction of improved turret-clocks, gas-meters, electro-magnets, silk-looms, and many other objects besides those already mentioned. In 1847, at the request of the contractor for the great tubes of the Conway Bridge, Mr. Roberts produced, almost *impromptu*, one of the most ingenious inventions known in metal working. This was the "Jacquard punching machine," an automatic tool of great power, whereby the rivet holes in a large plate are punched to any required pattern and pitch without need of templates or marking, and with a precision which enables any two of a thousand plates to be riveted together without subsequent correction of the rivet holes, as had always before been necessary. Without this invention the tubes of the Conway Bridge could not have been completed in time, while their strength was also increased and their cost of construction cheapened. The same punching machinery was employed in the construction of the Boyne Viaduct, the Victoria Bridge (the tubes of which are a mile and a quarter long) over the St. Lawrence, at Montreal, and for the great Jumna Bridge of the East Indian Railway.

In 1852, Mr. Roberts designed and made widely known his improved plans for ocean steamships of great size with the improved cross section of bow now adopted by our own and by the French naval authorities, and having besides double keels and twin screws, with independent engines, as applied with remarkable success in several steam-vessels of recent construction. These plans were for some time urged upon the Admiralty, and in 1855 they were submitted by Mr. Roberts, in person, to the Emperor of the French, who examined them critically, and in whose navy some of their peculiarities have been already adopted. In 1852, Mr. Roberts retired from the active pursuit of his profession, although, until within a few days of his death, he continued to practise as a consulting engineer. His habits and mode of life were marked with great simplicity, united with unceasing industry. A workman himself, he was ever the workman's true friend. Scientific and other institutions (especially in the locality of his early labours) found in him an earnest and liberal supporter. In his character, Mr. Roberts' integrity shone conspicuous. He abhorred a lie, and hated dissimulation with a heartiness which could only be best appreciated when he was opposed by the least departure on the part of others from what he believed to be the exact truth. His memory of what was essential to truth never faltered, and it has been said of him by Lord Campbell, Lord Brougham, and other eminent judges, that his answer would be always the same. At one time Mr. Roberts was in comfortable circumstances, but the loss he sustained by the forced sale of his property in Manchester, when its value had depreciated in consequence of the difficulties growing out of the stoppage of the American supply of cotton, left him with only his own exertions to depend upon. These he continued almost to the last hour of his long life, and only the day previous to his death, although in a state of extreme weakness, he dictated to his daughter, who had never left his side, a description of some improvements in the sewing-machine and in machines for cutting slate. Those who knew Mr. Roberts in private life spoke feelingly at the meeting of the noble example of filial devotion which his daughter's conduct had presented. Her graces and talents would have easily won for her a different position, but she preferred to sacrifice, not only her prospects, but even her health, as she has done, in order that her father's path to the grave might be smoothed by a daughter's affectionate care. Her case has excited an unusual degree of sympathy, and it is widely felt that the noblest memorial of the father's life and services will be a fitting provision for the daughter.

CORRESPONDENCE.

SUBMARINE TELEGRAPHY.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—It will, indeed, be lamentable if the lessons so often received, and so lately repeated, on the subject of submarine cables should be so ill understood, or so wilfully misapplied, as that another should be added to the long list of failures which now unhappily disgraces the annals of electric science.

With the account before us of what took place during the laying of the Persian Gulf cable—the separation, I mean, of the copper wire, while the spiral iron wires and the gutta-percha remained perfect—what are the inferences to be legitimately drawn?—to what conclusions do the circumstances inevitably lead us?

I am, I confess, at a loss to conceive how any man calling himself an engineer can avoid seeing that he has again received practical evidence of the truth of the theory so long brought to the notice of your readers, that in any structure where straight lines and spirals are found with a soft, or comparatively soft substance between them, the straight lines must bear the whole of the strain; the spirals in no way contribute to the strength. If compression of the comparatively soft gutta-percha or hemp can occur, then coincident elongation must be the result. There is no strength in any arch where the keystone is compressible. One would be disposed to imagine—one might even be inclined to affirm—that these propositions are self-evident. Why, then, is another £800,000 to be spent on a cable constructed on precisely these principles? Why are scientific men—men justly celebrated, one would suppose, for their general scientific knowledge—to be found supporting with the weight of their great names a cable which can only serve to exhibit the recklessness of contractors, and to exhaust alike the patience and the purses of telegraphic shareholders?

Is it not enough that the most unsuccessful undertaking in Europe, not, indeed, from any inherent defect in the magnificent structure, but from want of study or understanding the commercial and mechanical conditions of success—I refer to the Great Eastern—is it not enough that this should be joined to the next greatest failure, an Atlantic cable, by way of ensuring a magnified success? But we must be furnished with a cable such as I have described, such as has always hitherto failed, and such as no one in his senses can suppose will succeed because it measures an inch and a tenth in diameter, instead of five-eighths of an inch. I do write with strong feeling, for I can scarcely view such errors with patience; but on this subject at least I am not open to the reproach of taking an interested view. I have no cable of my own to propose, nor have I any interest other than that of the public to subserve.

It is not yet too late; the core is not yet subjected to the faithless compression of its weighty sheathing; and whether the said core be laid in its naked beauty, or straight steel wires be added to its outer strength, it will in either case, though not the best that could be made, be mechanically a more correct, statically a stronger cable, than it can ever be with the envelope now proposed, and I grieve to think approved by men who should have known better. Those who attempt to command success while they never seek to deserve it, need scarcely be surprised if disgraceful failure accompanies their every effort. Had the Persian Gulf cable been laid in 2,000 instead of 40 fathoms, we should now be lamenting another evidence of the truth of that which I here press on the attention of those interested—the shareholders—for there would have been little chance of raising it to effect the needful repair.

J. H. SELWYN.

TELEGRAPHIC NEWS.

THE DOUBLE-SPRING KEY.—Mr. Wm. Andrews, of the United Kingdom Telegraph Company, has recently introduced a very ingenious and efficient key for working the Pneumatic Relay. The arrangement is a substitute for the pump key, and is in fact an ordinary Morse with a double spring.

AN ELECTRIC LIGHT of unusual brilliancy was exhibited by Mr. Ladd, of Beak-street, London, on the top of St. Mary's-tower, Cambridge, during the recent visit of the Prince and Princess of Wales. The powerful voltaic battery was the one used for illuminating the Monument on the occasion of the marriage of their Royal Highnesses, March 10th, 1863. It would be interesting to know how far from Cambridge the light was visible.

VULCANIZED INDIA-RUBBER INSULATED WIRES.—A series of very interesting experiments upon the insulating capacities of a newly-designed and constructed core by Mr. William Hooper, of Pall-mall East and Mitcham Rubber Mills, were made on Thursday, the 16th inst., at Messrs. Reid Brothers' works, Wharf-road, City-road. The core was tested under a pressure of 6,700 lbs. on the square inch with the most satisfactory results. We are not informed, however, whether there were any *joints* in the length tested, as we have some doubts as to the permanency of *joints* made in vulcanized and virgin-rubber covered cores.

THE LATE EXPLOSION, LOSS OF LIFE, AND DESTRUCTION OF A TELEGRAPH STATION AT TRIPOLI.—Further particulars have been received relative to the late explosion of a Government powder magazine at Tripoli, on the 30th of May, by which more than 500 persons were at first said to have been killed, the greater portion consisting of Ottoman soldiers, in a barrack in the vicinity of the magazine. It appears from a later telegram, received by the Ottoman Consul-General at Malta from the Governor of Tripoli, that the number of victims was 150 only, that none of the population had, as first reported, sought refuge on board the shipping in the port, and that perfect tranquility prevailed among the people. Telegraphic communication had been temporarily suspended, from injury done to the station, and from the necessity of removing the instruments, which were covered with the débris.

THE INDIAN TELEGRAPH.—The *Calcutta Englishman*, of the 22nd April, says:—"Our Kurrachee correspondent said that Colonel Stewart intended returning to England soon, in order to arrange finally with the Sultan a convention for the use of the Turkish lines of telegraph. We further learn that Colonel Stewart will proceed to Constantinople first to carry out the details of the convention, which is to regulate the extent and description of control the English are to exercise over the Turkish lines. There is also a good deal to be done between Fao and Bagdad before the through line to England can be said to be in a satisfactory state. Nothing has yet been drawn up as to our control of the Turkish line, which commences at Bagdad, and nothing is to be done until Colonel Stewart reaches Constantinople. The cable has been laid down at Fao, and messages can be sent now to Europe in three days."—[We believe that Colonel Stewart, Sir Charles Bright, and the electrical and engineering staff, are expected to return to England about the 18th or 19th of the current month.—ED. T. J.]

TORPEDOES.—During the Chatham Siege Review, on the 11th instant, experiments were made with torpedoes, and the terrible effect is thus described:—"The besieged turned their attention to the boats, and sprung their first torpedo under water. These torpedoes, the most modern and most destructive engines of river warfare, were ranged in a line of six across the mouth of the creek. Some were made of tin cases, others were differently contrived on a new principle, on which it is unnecessary to be more explicit, and all were lit by the voltaic battery, carrying the spark through gutta-percha insulated wires into the centre of the charge. Though these torpedoes had been down a week in 30 feet of water, and contained charges varying from 100 lbs. to 160 lbs. of powder, yet not one failed to explode. The first, though a small charge, threw a great mass of water 60 feet into the air, and at this alarm all the boats drew rapidly away, as column after column of water and smoke rising to a towering height, and falling in a shower of foaming spray all over the creek, showed the imminence of the danger they had escaped. The last of the torpedoes fired was one containing 160 lbs. of powder, and the effect of this was apparently tremendous enough in force to have broken the back of a three-decker."

THE ATLANTIC TELEGRAPH COMPANY.—The steel of which the homogeneous wire for the Atlantic cable is being drawn by Messrs. Horsfall, of Birmingham, is being made by the Chillington Iron Company, of Wolverhampton. The first instalment of the wire was sent from Birmingham on Saturday last, *en route* for the works of Messrs. Glass, Elliot, & Co., at Greenwich. The wire will, at its thinnest point of tenuity (No. 13 guage) bear a strain of 1·040 lbs., according to the test of a machine which has been invented for the purpose by Mr. Deeley, Messrs. Horsfall's engineer. The wire, when brought into the works at Birmingham, from the rolling mills at Sheffield, measures about 200 yards per bundle, and is three-eighths of an inch in thickness. In Birmingham it has to pass through four drawings, by which it is reduced to No. 13 guage, or ·095 thick, and its length increased to 800 yards per bundle. After the drawing is over in Birmingham, the wire is boiled in oil before it is ready to be sent away from the works. The occasion of the despatch of the first instalment of the wire was one of considerable rejoicing at the works, and the thirteen railway trucks by which it was conveyed were drawn by horses decorated with ribbons and flowers.—[In the above paragraph, quoted from the *Engineer* of the 10th inst., we are informed that the wire at the thinnest point of tenuity (No. 13 guage) will bear a *strain* of 1·040 lbs., but we are not informed of the wire's contractile force after being subjected to various strains. The employment of steel wires applied spirally for the protection of the core in deep-sea telegraphs is a matter of considerable importance, as any one will find by reference to our own experiments on the tensile strength of cables. See Government Report of 1862.—ED. T. J.]

THE ELECTRIC VOTE REGISTER.—The Paris correspondent of *The Times* gives the following very interesting description of an electrical apparatus for recording the votes in the French Senate.—An experiment was tried on Tuesday at the Palace of the Luxembourg, in the presence of Baron Lacrosse, one of the Secretaries of the Senate, with an electrical apparatus, intended to replace the present mode of voting in the French Legislative Assemblies. The engineer who invented the apparatus began by placing 12 boxes, each provided with two finger keys, one white and the other black, on two benches. (The number of boxes is to be the same as the number of the members of the Assembly.) These boxes were connected by metallic wires, with what the engineer calls an indicating table, pierced with holes corresponding to the name of each of the voters. Two more holes, but larger, opening at the bottom of the table, are intended to give the addition of votes, for and against. This part of the apparatus is called the reckoner. The reckoner is moved by a button placed within reach of the President's hand. When the President announces that the ballot is to commence, each member of the Assembly presses the finger key, white or black, by extending his hand over his desk. A disc of the same colour instantly appears at the hole placed beside the name of the voter. When the President declares that the ballot is closed he touches the button placed under his hand, for the double purpose of preventing any further vote, and of setting in motion the machinery, which instantly performs the addition of the votes for and against. The Secretaries have then only to look at the reckoner and to transmit the numbers to the President. In case of a secret vote secresy is secured by an ingenious arrangement of the engineer, by which the vote is transmitted to any hole but that next the voter's name. The few persons who were admitted to be present at the experiment were greatly pleased with it.

TELEGRAPHY IN THE EAST.—A submarine line of telegraph is about to be carried out between India and Singapore by a private company, which has been in existence for some time, and was established to arrange a complete system of telegraphs between India, Singapore, China, and Australia. The India and Singapore telegraph will be the first line undertaken. The length of this line is 1,400 statute miles, or about 115 miles shorter than the Malta and Alexandria telegraph, which was laid three years ago. The cable between India (Rangoon) and Singapore will be laid in a depth not exceeding 50 fathoms, and this circumstance will enable it to be fished up without any difficulty for repairs, and will ensure the permanence of the work. Two intermediate stations will be established, one of which will be at Penang, and the longest section will not exceed 600 miles, which is shorter by 100 miles than the longest section on the Malta and Alexandria line. The proposed line will be a continuation of the telegraph to India, which will be shortly completed, but it has a value quite independent of the completion of telegraphic communication between this country and India. Singapore is one of the largest shipping ports of the world, and a submarine line is essentially adapted to accomodate ships in consequence of the proximity of the stations to the sea. The establishment of direct telegraphic communication between India and Singapore is alone of the utmost value, and will ensure a large return; such a line of telegraph will also reduce the distance to Hong-Kong, Shanghae, Batavia, and the Straits of Sunda, through which so large an amount of shipping passes on its way to and from China, to little more than the time occupied by the mail steamers between Singapore and those several points. The remunerative character of the Malta and Alexandria line gives good promise that the India-Singapore telegraph will be also highly profitable. It is a remarkable circumstance that a submarine cable can also be laid between Singapore, Hong-Kong, and Shangae, and also for the greater portion of the distance between Singapore and Australia, in a depth not exceeding 50 fathoms. Nothing can be more favourable than the sea bottom and depth in those seas, as shown on the Admiralty charts, for the development and permanence of submarine telegraphy.

ROYAL ASTRONOMICAL SOCIETY.—Warren de la Rue, Esq., F.R.S., President of the Royal Astronomical Society, entertained a numerous and distinguished company at a *soirée*, at Willis's Rooms, on Saturday evening, the 11th instant. Among the company present were his Eminence Cardinal Wiseman, Bishop Colenso, the Dean of Chester, the Earl of Caithness, Lord Wrottesley, Lord Wensleydale, the Master of the Mint, Sir John Bowring, Sir Charles Locock, Sir Henry Holland, Admiral Sir George Sartorius, Sir E. Belcher, Sir A. S. Waugh, Sir Roderick Murchison, Sir Henry Rawlinson, the Right Hon. C. P. Villiers, M.P., &c. A large number of most interesting astronomical and other articles were exhibited, and during the evening afforded much pleasurable scrutiny. The President (Mr. de la Rue) exhibited photographs and drawings of the planets, a photograph of the eclipse, a photograph of the moon, 38 inches in diameter, and a collection of Turner's paintings. From the Astronomical Society some exceedingly interesting articles were sent. The Kew Observatory sent, amongst other articles, the glasses and original mountings of Huggens's

serial telescope (120 feet focus), and the model of the tower which Mr. de la Rue proposed erecting there in order to view Saturn through glasses. The London Institution, the Rev. Professor Selwyn, Professor Phillips, of Oxford; T. W. Burr, Esq., Rev. F. Howlett, Alex. S. S. Herschel, Esq., J. Nasmyth, Esq., C. W. Siemens, Esq., E. W. Cooke, Esq., A. M'Cullum, Esq., Owen Jones, Esq., Vice-President of Society of Architects; H. Warren, Esq., President of New Society of Painters in Water Colours; Messrs. Lloyd Brothers, Henry Swann, Esq., Thos. Woolner, Esq.; Morton Edwards, Esq.; S. M. Drach, Esq.; Dr. Lee; Admiral Smyth; E. W. Brayley, Esq., Henry F. Holt, Esq.; C. V. Walker, Esq.; Hamilton Field, Esq.; W. Tite, Esq., M.P.; Captain George, R.N.; J. Hart, Esq.; J. T. Barber, Esq.; and H. Perigal, jun., Esq., furnished very interesting articles in the way of telescopes, autographs, astronomical and other diagrams, meteorites, and models, as well as paintings, photographs, instruments, &c. Professor Wheatstone supplied a pair of indicating instruments and a magnetic typo-printing telegraph. The latter was much admired, as being a very useful and ingenious contrivance. Lieutenant-Colonel W. F. De la Rue's piece of the flagstaff of Fort Sumter, a fragment of a Parrott-shell fired against the fort, and brick dislodged from the fort (authenticated by General Beauregard's autograph) were much sought after; as was also Professor Roscoe's new magnesium lamp, which has been employed for the production of photographic portraiture by night. Dr. Giles exhibited some original sketches by Thackeray, made in 1832, before the lamented author was known to fame. The directors of the Patent Electric Signal Company exhibited their recently patented invention for indicating, by means of electricity, the exact position of distant or auxiliary signals, points, and switches. C. Frodsham, Esq., exhibited a number of astronomical clocks, chronometers, watches, &c. A telescope of new construction, on Gauss's principle, and embodying the seven desiderata set forth by Gauss, was exhibited by Dr. Steinheil, of Munich. A series of microscopes, exhibited by Messrs. Smith, Beck, & Beck, Messrs. Powell & Lealand, J. How, Esq., and T. Ross, Esq., were much in requisition, and elicited a good deal of admiration. S. Heighly, Esq., Octavius Morgan, Esq., C. Heisch, Esq., A. F. Claudet, Esq., J. F. Abel, Esq., John Young, Esq., Professor Tennant, Dr. Wright, S. W. Silver, Esq., Henry Lowcock, Esq., W. D. Haggard, Esq., Richard Abbatt, Esq., Benjamin Scott, Esq., J. S. S. Glenny, Esq., Messrs. Mertz, Munich, E. Wheeler, Esq., Thomas Ross, Esq., W. Ladd, Esq., Messrs. Cooke & Sons, York, Messrs. Horne & Thornthwaite, Messrs. Elliott & Brothers, J. P. Casella, Esq., P. Adie, Esq., Messrs. Troughton & Simms, J. H. Dallmeyer, Esq., Messrs. Hopkins & Williams, J. Browning, Esq., and Mr. Silver, of the "India Rubber Works and Telegraph Cable Company," were amongst the other exhibitors. Some experiments with the electric light evoked general admiration.

MISCELLANEA.

Spectral Ray of Thallium Paralysed by that of Sodium.—It appears that if thallium be present in small proportions in a compound containing chloride of sodium, the action of the ray characteristic of the latter is so powerful that the thallic ray remains unperceived. Hence, although the thallic ray be not observed in the solar spectrum, it by no means follows that the metal itself does not exist in the sun. This is a fact of great importance, not only in regard to ordinary chemistry, but as it bears on toxicology. For in an analysis (spectral) of the animal tissues or liquids, one is certain to find chloride of sodium in abundance, and therefore, were thallium present in small proportions, it would escape detection by this method. If it be required to examine mineral waters and such-like for thallium, it will be necessary to separate the metal in the first instance from the excess of soda; this may be done by one of the methods pointed out by M. Lamy, viz., either depositing it on zinc, or reducing it by galvanic means, or by precipitating it with sulphide of ammonium or iodide of potassium.

Gas Engines in France.—*Le Petit Journal*, of Paris, in a long article sparkling with French vivacity, on the uses of the Moteurs Lenoir, states that large numbers of these engines are employed for various purposes in Paris. The writer discourses thus:—"We have been to the Grand Hotel. It is not far; and we have examined the Moteurs Lenoir labouring for the comfort of the thousand travellers lodged in that caravansery of the great world. There is one which supplies all of the water for the hotel, from the cellar to the garret; another raises the dishes from the basement to the fourth story; another turns the machine for breaking the ice and cooling the sillery, the cliquot. Six men were formerly required, half naked and panting, to operate this machine which the little motor turns like a top. Another motor raises to their respective stories the travellers comfortably seated in a saloon disposed for this perpendicular voyage; another raises the baggage, and all this without noise, without fire, without smoke. The complaisance of the mechanician charged in the hotel with all of the mechanical service, enabled us to see how these motors put themselves in operation, and stop themselves instantaneously. What gives to them the movement—origin of their power? It is gas, which an electric spark inflames in the body of the piston. That gas—it is that which the immense *Compagnie Parisienne* distributes in all the city. It comes to feed the Lenoir motor as it would feed a burner or a stove."

Formation of Iron by Metallurgical Insects.—A Swedish naturalist, M. Sjogreen, has recently published a curious memoir on an iron mineral which is, he contends, the direct work of infusorial animalculæ, living in the midst of sweet water. This ferruginous mineral, known under the name of lake ore, is sufficiently abundant in certain Swedish water-courses to be submitted to treatment in ironworks. The memoir of M. Sjogreen was composed with more especial reference to certain specimens of minerals shown in the International Exhibition of London, in 1862. A lake in his neighbourhood had fallen much below the ordinary level, and enabled him to follow the evolution of the mineral. The bottom of the lake was in part laid bare, from the extreme lowness of the water, but there still existed depressions filled by water, and occupied by insects or infusorial metallurgists. These depressions presented a strange and marvellous spectacle. At the bottom of one, which was somewhere about three feet in diameter, small creatures of different sizes agitated themselves on the mineral, some being visible to the naked eye, while the others were so small that without a magnifying glass it would have been impossible to discern them. All were actively engaged in enclosing themselves in a metallic envelope, just as the caterpillar encases itself in a cocoon, and the work seemed to the spectator to be effected in a systematic manner. The iron exists in the waters in a soluble state, or rather, the waters borrow it from the surrounding lands. Lake mineral is produced with considerable rapidity; in certain lakes from which there had been extracted twenty-six years previously all the metallurgical crop, there was again found after this yield a fresh harvest of almost equal abundance.

PATENTS.

APPLICATIONS FOR LETTERS PATENT.

1412. H. A. Bonneville, improvements in telegraphic printing apparatus.—A communication.

1458. J. McElroy, improvements in electro-telegraphic apparatus, and in instruments for preparing the transmission of electric telegrams.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

1308. G. Schaub, an improved mode of transmitting currents of electricity for telegraphic purposes.

1345. P. Deeley, a new or improved machine for testing the strength of wire.

PATENTS SEALED.

3245. J. G. Rowe, improved means of communication between the guard and engine-driver of a railway train.

3208. F. N. Gisborne, improvements in the means of communicating signals on board ship, on railways, and for other purposes.

3252. F. Walton, improvements in telegraphic cables.

PRICES CURRENT OF INSULATING MATERIAL.

Gutta Percha, as imported.

Genuine, fine and good	2/2 to 2/6	per lb.
Good re-boiled	1/6 to 1/8	„

JOINTS IN THE INSULATED CORES OF SUBMARINE CABLES.

IN conversation recently with a gentleman who has ever manifested a lively interest in submarine telegraphy, the difficulty of effectually splicing lengths of rubber insulated cable came under consideration, when, without the remotest intention of perpetrating a joke, our friend remarked, "Well, as it appears inevitable that we must have 'joints,' every precaution should be taken to have them 'well done.'" The importance of the observation has been fully borne out by the lamentable failures which have been found to result from defective insulation, manifesting itself in the jointings after the submersion of cables. Within the last few years numerous materials have been proposed for insulating purposes, and have been subjected to electrical tests, mostly in short lengths, with the most favourable results. We have had on several occasions to investigate the insulating properties of such materials, and more especially with regard to the practicability of making efficacious joints therein.

In the Report of the Submarine Telegraph Committee, speaking of india-rubber covered wire, it is stated that "the joints of the spirally twisted slip should closely adhere, otherwise in every place of imperfect contact a fault would be generated." As an illustration of this fact, the following account of some recent tests will be found both interesting and instructive.

The length of cable tested was about sixteen miles, coiled and immersed in water in a large well or tank. The construction of the cable is described as follows:—The copper wire or conducting strand, about 270 lbs. per statute mile, covered or insulated with 165 lbs. per statute mile of india-rubber; the first coating being of pure virgin rubber, and the remaining coatings of masticated rubber, and the complete core served with the best Russian hemp, saturated with Stockholm tar, then furnished spirally with twelve No. 8 galvanized iron wires.

The battery employed for the electrical tests consisted of 120 elements of Daniell's, and the instrument used was Mr. W. T. Henley's standard galvanometer, a very sensitive and accurate instrument. One end of the cable being insulated, and the other attached to the binding screw of the galvanometer, and through it to the copper pole of the battery, the zinc pole being in connection with earth, the loss of insulation, as indicated on the instrument, was 7·5° with the copper pole, and with the zinc pole, 21°, increasing in two minutes to 28°; the poles were reversed, when the copper gave a loss of 9°, decreasing in one minute to 8°.

The battery power was then reduced to 60 elements. The loss on the zinc was 14°, and on the copper 9°, and when reduced to 30 elements, the loss on zinc was 4°, and on copper 3°. After a short interval the following additional tests were made:—

30 elements.	°
Copper to cable	2 loss
Zinc to cable	2·75
60 elements.	°
Zinc to cable	6 loss
Copper to cable	3·25
120 elements.	°
Zinc to cable	56·5 loss
Copper to cable	21
60 elements.	°
Copper to cable	10·75 loss
Zinc to cable	53·

The electrolytic action of the current upon the imperfect joints is apparent, and no doubt, had the experiments been continued, the destruction of the insulation would have been complete, and irremediable had the cable been submerged in great depths. When the same cable was tested in one mile lengths the aggregate loss on twenty miles, with 504 elements, did not exceed ·3°, as will be found from the following table published at the time:—

Date of Testing.	Temperature of Water.	Number of length (1 mile).	Loss of Insulation in Vacuo.	Loss of Insulation under Pressure.

We propose now to place before our readers the opinion of a gentleman of great practical experience, on electrolysis. Mr. C. F. Varley, in his evidence before the Submarine Telegraph Committee, gives the following instances which came under his observation. He says:—

"I have frequently observed this peculiarity of the positive current sealing up a fault; it acts in different cases in different ways. In sea water it oxidizes the copper wire, and also produces a subchloride of copper, which renders the surface non-metallic, and to a certain extent insulating. The current escaped, and this fault gradually got worse and worse, until it became what we technically term dead earth—that is, so much of the current flowed into the ocean, that we could get no intelligible signals through. Some years since a wire between the Admiralty and our Strand office was three times reported by our man who repairs the street wires to be good, and as often reported bad by myself. I made an appointment with him to test the wire. I found that he had tested with the negative. That wire was a peculiar instance of the effect which very frequently occurs, but it was very rapid, so rapid that the moment the positive current was applied the wire instantly insulated, and the moment the negative was applied it instantly gave way, and became dead earth. As we reversed the current the wire was either insulating or giving earth. Ordinary gutta-percha covered wire often shows to a small extent the same action; its insulation always improves slightly under the influence of a powerful positive current; and, generally speaking, becomes bad again to a certain extent with the negative current. I am very much inclined to attribute this phenomenon to the existence of water in the pores of the gutta-percha, for gutta-percha, as at present manufactured, is not free from moisture. Wherever you get this variation, it is, in my opinion, an indication of electrolytic action going on."

We intend to return to this subject in a future number.

ON A MAGNETIC EXPERIMENT.

THE 1863-4 session of the Royal Institution was brought to a close on the 10th instant by a lecture with the above title by Professor Tyndall. Professor Tyndall spoke as follows:—"There are two words which are very often employed in scientific writings—matter and force. The definition of each involves the conception of the other. We know nothing of force save through its operations upon matter, and we know nothing of matter save through the manifestations of its force. The nature of any force must therefore be sought in the material changes which it is competent to produce. Some years ago I felt a great interest in the subject of magnetism, and in those years I devised an apparatus to enable me to investigate certain mechanical effects which accompany the act of magnetization. I wished to apply this apparatus to diamagnetic bodies as well as paramagnetic ones—to bodies such as bismuth, as well as to bodies such as iron. I intend this evening to show you the action of this instrument, and to give, if I can, some explanation of the experiments of others which have been confirmed by my own.

"Let us pass quickly in review the excitation of this wonderful power of magnetism. Here is a strong horseshoe magnet set upright, and here is a bent bar of steel, whose arms are the same distance apart as those of the horseshoe magnet. I draw the bent steel bar over the ends, or the poles, as they are called, of the magnet. It suddenly obtains the power of attracting this iron keeper and holding it fast. I reverse the stroke of the steel bar: its virtue has now disappeared; it is no longer competent to attract the keeper. I continue the stroke of the steel bar in the last direction, and now it is again competent to attract the iron: thus I can at will magnetize and demagnetize this bent piece of steel.

"Here is a noble, permanent magnet constructed by Logemann, of Haarlem, and competent to carry a great weight. Here, for example, is a dish of iron nails which it is able to empty. At the other side of the table you observe another mass of metal, bent like the Logemann magnet, but not, like it, naked. This mass, moreover, is not steel, but iron, and it is surrounded by coils of copper wire. It is intended to illustrate the excitement of magnetism by electricity. At the present moment this huge bent bar is so inert as to be incapable of attracting a single grain of iron. I now send an electric current through the coils that surround it, and its power far transcends that of the steel magnet on the other side. It can lift fifty times the weight. It holds a 56 lb. weight attached to each of its poles, and it empties this large tray of iron nails when they are brought sufficiently near it. I interrupt the current; the power vanishes, and the nails fall.

"Now the magnetized iron cannot be in all respects the same as the unmagnetised iron. Some change must take place among the molecules of the iron bar at the moment of magnetization. And one curious action which accompanies the act of magnetization I will now try to make sensible to you. Other men laboured, and we are here entering into their labours. The effect I wish to make manifest was discovered by Mr. Joule,* and was subsequently examined by De la Rive and Wertheim, Marian, Matteucci, Wartmann. It is this. At the moment when the current passes through the coil surrounding the electro-magnet, a clink is heard emanating from the body of the iron, and at the moment the current ceases a clink is also heard. In fact, the acts of magnetization and demagnetization so stir the atoms of the magnetized body that they in their turn can stir the air and send sonorous impulses to our auditory nerves.

"I have said that the sounds occur at the moment of magnetization, and at the moment when magnetization ceases; hence if I can devise a means of making and breaking in quick succession the circuit through which the current flows, I can obtain an equally quick succession of sounds. I do this by means of a contact-breaker which belongs to a Ruhmkorff's induction coil. Here is a monochord, and a thin bar of iron stretches from one of its bridges to the other. This bar is placed in a glass tube, which is surrounded by copper wire. I place the contact-breaker in a distant room, so that you cannot hear its noise. The current is now active, and every individual in this large assembly hears something between a dry crackle and a musical sound issuing from the bar in consequence of its successive magnetization and demagnetization.

"Hitherto we have occupied ourselves with the iron which has been acted upon by the current. Let us now devote a moment's time to the examination of the current itself. Here is a naked copper wire, which is quite inert, possessing no power to attract these iron filings. I send a voltaic current through it; it immediately grapples with the filings, and holds them round it in a thick envelope. I interrupt the current, and the filings fall. Here is a compact coil of copper wire which is overspun with cotton to prevent contact between the convolutions. At present the coil is inert; but now I send a current through it; a power of attraction is instantly developed, and you see that it is competent to empty this plate of iron nails.

"Thus we have magnetic action exhibited by a body which does not contain a particle of the so-called magnetic metals. The copper wire is made magnetic by the electric current. Indeed, by means of a copper wire through which a current flows, we may obtain all the effects of magnetism. I have here a long coil, so suspended as to be capable of free motion in a horizontal direction; it can move all round in a circle like an ordinary magnetic needle. At its ends I have placed two spirals of platinum wire which the current will raise to brilliant incandescence. They are glowing now, and the suspended coil behaves in all respects like a magnetic needle. Its two ends show opposite polarities; it can be attracted and repelled by a magnet, or by a current flowing through another coil; and it is so sensitive that the action of the earth itself is able to cause it to set north and south.

"There is an irresistible tendency to unify in the human mind; and, by aid of imagination, we transfer the conceptions of the visible world to the invisible. In accordance with our mental constitution we desire to reduce phenomena which are so much alike to a common cause; and hence the conception of the celebrated Ampère that a magnet is simply an assemblage of electric currents. Round the atoms of a magnet Ampère supposed minute currents to circulate incessantly in parallel planes; round the atoms of common iron he also supposed them to circulate, but in all directions—thus neutralizing each other. The act of magnetization he supposed to consist in the rendering of the molecular currents parallel to a common plane, as they are supposed to be in the case of the permanent magnet.

"This is the celebrated theory of molecular currents propounded by Ampère. You observe it consists in the application of conceptions obtained from sensible masses of matter to insensible or atomic masses. Let us follow out this conception to what would appear its legitimate consequences. I have said that we obtain both attractions and repulsions from electric currents: all these effects are deduced from one law, which is, *that electric currents flowing in the same direction attract each other, while, when they flow in opposite directions, they repel each other*. Let me illustrate this law rapidly. Here are two flat coils suspended facing each other, and about eight inches apart. I send a current through both, causing it to flow through them in the same direction; the coils instantly clash and cling together in virtue of their mutual attraction. I now reverse the current through one of them, and they fly a yard asunder, in virtue of their mutual repulsion. And now one of them twists its suspending wire so as to turn its opposite face to the other coil; the currents are now again in the same direction, and the coils clash and cling as in the first instance. Imagine, then, our molecular currents flowing round the atoms of this iron bar in planes perpendicular to the length of the bar. From the law just enunciated we should infer the mutual attraction of those currents; and from this attraction we should be disposed to infer the *shortening* of the bar at the moment of magnetization. Here, for example, is a coil of copper wire suspended vertically; the end of the coil dips into this little basin of mercury. From a small voltaic battery behind I send a current through the coil; and, because it passes in the same direction through all its convolutions, they attract each other. The coil is thereby shortened; its end quits the mercury with a spark; the current ceases; the wire falls by its own gravity; the current again passes, and the wire shortens as before. Thus you have this quick succession of brilliant* sparks produced by the shortening of the wire and the interruption of the current as it quits the mercury.

"Is it a fact, then, that an iron bar is *shortened* by the act of magnetization? It is not. And here, as before, we enter into the labours of other men.

"Mr. Joule was the first to prove that the bar is *lengthened*. Mr. Joule rendered this lengthening visible by means of a system of levers and a microscope, through which a single observer saw

* The sound, I find, was first noticed by Mr. Page.—I. T., 16th June.

* Rendered brilliant by the introduction of a coil of wire and a core of soft iron into the circuit.

the action. The experiment has never, I believe, been made before a public audience; but the instrument referred to at the commencement of this lecture will, I think, enable me to render this effect of magnetization visible to everybody present.

"Before you is an upright iron bar, two feet long, firmly screwed into a solid block of wood. Sliding on two upright brass pillars is a portion of the instrument which you see above the iron bar. The essential parts of this section of the apparatus are, first, a vertical rod of brass, which moves freely and accurately in a long brass collar, the lower end of the brass rod resting upon the upper flat surface of the iron bar. To the top of the brass rod is attached a point of steel, and this point now presses against a plate of agate, near a pivot which forms the fulcrum of a lever. The distant end of the lever is connected, by a very fine wire, with an axis on which is fixed a small circular mirror. If the steel point be pushed up against the agate plate, the end of the lever is raised; the axis is thereby caused to turn, and the mirror rotates. I now cast a beam from an electric lamp upon this mirror; it is reflected in a luminous sheaf, fifteen or sixteen feet long, and strikes our screen, there forming a circular patch of brilliant light. This beam is to be our index; it will move as the mirror moves, only with twice its angular velocity; and the motion of the patch of light will inform us of the lengthening and shortening of the iron bar.

"I employ one battery simply to ignite the lamp. I have here a second battery to magnetize the iron bar. At present no current is passing. I make the circuit, and the bright image on the screen is suddenly displaced. It sinks a foot. I break the circuit: the bar instantly shrinks to its normal strength, and the image returns to its first position. I make the experiment several times in succession: the result is always the same. Always when I magnetize the image descends, which declares the lengthening of the bar; always when I interrupt the current, the image rises. A little warm water projected against the bar produces the same effect as magnetization. This, I believe, is the first time that this action has been seen by a public audience.

"I have employed the same apparatus in the examination of bismuth bars, and, though considerable power has been applied, I have hitherto failed to produce any sensible effect. It was at least conceivable that complementary effects might be here exhibited, and a new antithesis then established between magnetism and dia-magnetism.

"No explanation of this action has, to my knowledge, been offered, and I would now beg to propose one which seems to be sufficient. I place this large flat magnet upon the table, over it I put a paper screen, and on the screen I shake iron filings. You know the beautiful lines in which these filings arrange themselves—lines which have become classical from the use that has been made of them in this Institution; for they have been guiding threads for Faraday's intelligence while exploring the most profound and intricate phenomena of magnetism. These lines indicate the direction in which a small magnetic needle sets itself when placed on any of them. The needle will always be a tangent to the magnetic curve. A little rod of iron, freely suspended, behaves exactly like the needle, and sets its longest dimension in the direction of the magnetic curve. In fact, the particles of iron filings themselves are virtually so many little rods of iron, which, when they are released from the friction of the screen by tapping, set their longest dimensions along the lines of force. Now, in this bar magnet the lines of force run *along the magnet itself*, and, were its particles capable of free motion, they would also set their longest dimensions parallel to the lines of force—that is to say, parallel to the length of the magnet. This, then, is the explanation which I would offer of the lengthening of the bar. The bar is composed of irregular crystalline granules, and, when magnetized, these granules tend to set their longest dimensions parallel to the axis of the bar. They succeed partially and produce a microscopic lengthening of the bar, which, suitably magnified, has been rendered visible to you.*

"Perhaps you do not see the magnetic curves from your present position, but I will enable you to see them. I have here an electric lamp turned on its back, and from it a vertical cylinder of light now issues. Over the aperture of the lamp I place two small bar magnets, enclosed between two plates of glass. The vertical beam is received upon a looking-glass which reflects it on to the screen. In the path of this reflected beam I place a lens, and thus obtain upon the screen a magnified image of the two small bar magnets. And now I sprinkle this fine iron sand on the plate of glass, and you see how it arranges itself under the operation of the magnets. A most beautiful display of the magnetic curves is now before you. And you observe, when I tap the glass, how the particles attach themselves by their ends, and how the curves close in upon each other. They try to attach themselves thus in the solid iron bar: the consequence is that the longitudinal expansion is exactly counterbalanced by the transverse contraction, so that the *volume* of the bar remains unchanged.

"But can we not bring a body with moveable particles within an electro-magnetic coil? We can. And I will now, in conclusion, show you an experiment devised by Mr. Grove, which bears directly upon this question, but the sight of which, I believe, has hitherto been confined to Mr. Grove himself. At all events, I am not aware of its ever having been made before a large audience. I have here a cylinder with glass ends, and it contains a muddy liquid. This muddiness is produced by the magnetic oxide of iron which is suspended mechanically in the liquid. Round the glass cylinder I have coiled five or six layers of covered copper wire; and here is a battery from which a current can be sent through the coil. First of all, I place the glass cylinder in the path of the beam from our electric lamp, and by means of a lens cast an image of the end of the cylinder on the screen. That image at present possesses but feeble illumination. The light is almost extinguished by the suspended particles of magnetic oxide. But, if what I have stated regarding the lines of force through the bar of magnetized iron be correct, the particles of the oxide will suddenly set their longest dimensions parallel to the axis of the cylinder, and also in part set themselves end to end when the current is sent round them. More light will be thus enabled to pass; and now you observe the effect. The moment I establish the circuit, the disc upon the screen becomes luminous; I interrupt the current, and gloom supervenes; I re-establish it, and we have a luminous disc once more.

"The apparatus, as I have stated, was really invented to examine whether any mechanical effect of this kind could be detected in diamagnetic bodies; but hitherto without result. And this leads me to remark on the large ratio which the failures of an original inquirer bear to his successes. The public see the success—the failure is known to the inquirer alone. The encouragement of his fellow-men, it is true, often cheers the investigator, and strengthens his heart; but his main trials occur when there is no one near to cheer him, and when, if he works aright, he must work for duty and not for fame. And this is the spirit in which work has been executed in this Institution, by a man who has, throughout his life, turned a deaf ear to such allurements as this age places within the reach of scientific renown; and it behoves every friend of this Institution to join in the wish that *that* man's spirit may continue to live within its walls, and that those who come after him may not shrink from his self-denial while endeavouring to merit a portion of his fame."

* My assistant, Mr. Barrett, has just drawn my attention to a paper by M. De la Rive, in which this explanation is given. To him, therefore, belongs the entire credit of it.—J.T., June 18.

TELEGRAPHY IN TURKEY.

In a letter from Constantinople, dated 9th June, the correspondent of the *Daily Telegraph* thus adverts to the condition of the telegraph in the Ottoman dominions:—

"According to the information received here, the opening of the telegraph through to India will very shortly take place. As very little appears to be known as to the actual condition of the telegraphic service in this country, it may be opportune to give some particulars about it. Communication between the Ottoman capital and Western Europe passes through Vienna. From that city to Constantinople there are two distinct lines, one passing by Semlin and Belgrade to Adrianople, the other by Toultscha, Kustendjie, and Varna. There is a third line to Adrianople by Bucharest. By the opening of the submarine line between Avlona and Otranto, in Italy, the Turkish telegraph service will be in direct correspondence with the West, without going through Servia or the Moldo-Wallachian Principalities, where, at present, every conceivable obstruction is offered to the transmission of messages. Great as the disadvantages arising from this may be, they are but of trifling importance compared with the manner in which the Turkish telegraph service is itself performed. The original construction of the lines was of the most defective description, the materials used being very inferior. The tract of country chosen was selected apparently because of its presenting the greatest difficulties; since it is impossible for any proper supervision to be exercised as to the condition of the wires in severe weather, the lines passing over the steepest and most inaccessible hills, and

through valleys which might altogether have been avoided by the exercise of ordinary attention. This state of things is made worse by a very inadequate inspection, by men who are both too few in number, wretchedly paid, and generally incompetent. There is further to be considered the very frequent and arbitrary occupation of the wires by the Government, both on the Asiatic and European sides, interrupting, on many occasions, business of the most pressing nature, for the transmission of some trivial communication, which would lose nothing by a short delay. It may be imagined that, as the service is in the hands of Government, much depends upon the director-general of the department. Unfortunately, this official is in the unenviable position of holding office on such a poor tenure that it may be said he has a daily apprehension of being turned out and replaced by one of those numerous intriguers who swarm about the cabinets of the Ministers, or work through the more effectual influence of the Harem—the great bane of the country. The present director-general, Dihran Bey, an Armenian, is a weak vacillating man, appears to live in constant fear of causing trouble to the Turkish authorities, and is aware of their jealousy.

"The distance from this to Bagdad is 1,330 miles, and from the latter to Bussorah, where our Indian submarine line begins, 400 miles. From this city to Avlona the distance is 706 miles, making a total of 2,436 miles which the Indian messages will have to pass through Turkey. The lines from this to the other European Turkish frontier stations are—to Nissa, 440 miles; Rustchuk, 340; Toulcha, 355. It is probable that the line viâ Avlona will be the one selected for the Indian messages, both from its being more direct and avoiding the inconvenience already referred to. But, whatever prospect there may be of the regular working of the European line, it is very different with the Asiatic section from Scutari to Bussorah. The whole of this distance is entrusted to the inspection of four persons, two of whom are Englishmen, who, from the immense distance they have to traverse, even with the present limited work, find it impossible to keep the line in good order. Caretakers (chaouses,) each of whom has to provide and keep a horse out of his pay of 300 piastres (£2 14s.) per month, and whose beats extend to a two-hours' ride, have the watching of the wires, but are not able to repair damages. The chiefs of stations, and all other employés in Asia, are Turks, whose lazy habits and incompetency need not be wondered at when the smallness of their pay is considered; so there is every reason to apprehend that our Indian service is likely to be seriously retarded by depending upon such men. It has been proposed to the Turkish Government to employ a larger staff of European inspectors and electricians, but the natural jealousy of employing foreigners, in preference to their own subjects, stands in the way. The course the India Office ought to have taken, and which they will be obliged to come to eventually, was to obtain a concession for a separate wire from Bussorah to Avlona for the exclusive use of the India service. The advantages of such an arrangement are manifold, as the perfect control which would be thus secured would ensure despatch, regularity, and correctness; while to allow the service to remain in Turkish hands will only involve a serious amount of confusion. The India Office appears to have been at some loss how to act. Instead of securing as agents—to look to the efficiency of the service—persons acquainted with the country, its language, customs, and people, gentlemen have been sent out with the anomalous official designation of traffic managers—a post which the Turks cannot understand the nature of, from the fact that the officials in question will not have the slightest control over or connection with the traffic. A better course to pursue would have been to have endeavoured to employ, instead of these persons, who have no other qualification than their knowledge of some European language and electrical manipulation, the best local available means. For the direction of this service no better selection could have been made than Mr. O'Conner, the present able director of the Ottoman European telegraph service here. His long experience of the country, together with his fitness in every other respect, would have enabled him to organise telegraphic communication with India, so far as Turkey is concerned, vastly more efficient than it will be. I may mention, as proof of Mr. O'Connor's administrative ability, a fact that is of no slight interest. Some time since he was appointed to the charge of a part of the Asiatic line, when his post as director of the European service was filled successively by two persons, under whose mismanagement the service fell into the direst disorder, the employés becoming so corrupt that there was no longer any dependence to be placed on the secrecy which, of course, is essential in the transmission of messages. Matters went on thus to so flagrant an extent, that public indignation was aroused, and the Government re-appointed Mr. O'Connor to the directorate; in less than a month he effectually put down the corruption of the employés, rendered the service efficient, and restored public confidence. Such a man, possessed of energy, tact, thorough knowledge of the country, and how to manage its people, would, as agent for the India Office in this country, have been worth a host of the nondescript traffic managers sent out with no defined idea as to what they are to do. Already a "difficulty" has arisen. Mr. W. L. Courtenay, the India Office "traffic manager," recently arrived here, applied for the use of an office in the building occupied by the European telegraph department; this was refused, and one offered at the Scutari station, on the Asiatic side of the Bosphorus. Of course this has been declined, and so the traffic manager's office is opened in his private house, situated at an inconvenient distance from the other offices. At the Bagdad end of the line we are likely to have less cause of complaint, as our Consul-General there, Colonel Kemball, C.B., who is to have a special supervision of the service in that quarter, may be depended upon to see things go right.

"While on the subject of the Turkish telegraph, I may mention that some time since an application was made by Mr. Reuter to farm the European line, but the Porte declined both his and other offers. The matter has been again revived, and a renewed attempt is now being made to lease the line. Although this may be considered as a mere matter of internal policy, it is not probable that it will be favourably looked upon by the European powers. The impression in well-informed circles is, that the Porte will now, as before, decline to entrust the telegraph into foreign hands."

THE PERSIAN GULF TELEGRAPH EXPEDITION.

Her Majesty's steamer Coromandel, commanded by Lieutenant G. O. B. Carew, I.N., the senior Bombay marine officer with the above expedition, arrived in Bombay harbour on the 20th inst., with Lieut.-Colonel Patrick Stewart, R.E., the Director General of the Government Telegraph to India, and Sir Charles Bright, of the eminent engineering firm of Bright and Clark, each accompanied by the majority of his staff; that of Colonel Stewart consists of Captain Colvin Stewart, and Messrs. Brashes and Ponsonby Adair. Commander Bradshaw, R.N., of her Majesty's steam frigate Severn, and Mr. A. P. Young, of her Majesty's late Indian navy, who have been engaged during the laying of the submarine cable in preparing a very accurate chart of its course and position, have remained in Kurrachee to complete the chart, without which any repairs which the cable may hereafter require could scarcely be executed. Sir Charles Bright's staff consists of Messrs. Webb, Laws, Lambert, Woods, Alexander, Mosely, Donovan, and Crooks.

As our readers are already aware, the work for which the Persian Gulf expedition was sent out has been most successfully completed. A submarine telegraph cable has been laid from Kurrachee westwards along the Mekran coast of Beeloochistan, across the Gulf of Oman, up Malcolm's Inlet to Mussendom, over the isthmus called by the surrounding inhabitants Muklub, then submerged again on the other side, carried through the Elphinstone Island Repeating-station, and down Elphinstone Inlet to the Persian Gulf, along the bottom of which it creeps to Bushire, just "puts in an appearance" there, and starts off again to the Khor-ab-Dallah at the head of the Gulf, whence it wallows in the mud up to Fao on the Shat-el-Arab, the broad stream by which the Euphrates and Tigris discharge their waters in common into the Persian Gulf. At Fao the cable terminates in an office on board the hulk Hyderabad, the Turkish Government having failed to fill its engagement to have a building erected there before the arrival of the cable.

Thus the British Government has fulfilled to the letter its engagement to carry an electric wire from India to the confines of the Turkish possessions in Asia Minor; but how has the Turkish Government done its part? We regret to be obliged to state, that though furnished by us with every possible assistance, both in *personnel* and *materiel*, yet from total loss of that energy which rendered them once the scourge of the world, and by inability to control the wild tribes—nominally their subjects, but really independent—through whose country they were to have carried the land wires, they have left us in a position very little better, as regards communication with Europe, than we were before the Persian Gulf cable had been laid. At least for some months to come we cannot hope to send messages to England in less than six or eight days, or to receive them in less than four or five, although a message can be sent from Kurrachee to Fao, and the answer received, in half an hour.

The points on the projected Turkish lines between which no telegraph has been erected at all as yet, are Medina, near the junction of the Tigris and Euphrates, and Diwaniyeh, about 100 miles from Bagdad. Medina is over 100 miles from the end of our submarine cable at Fao, so that of the 380 miles from Fao to Bagdad upwards of 150 remain to be completed. Nor can any hope be entertained that this will be done before the end of the year, as the country is in a state of anarchy, and the Arabs refuse to allow the work to be carried on, while the jealousy of the Turkish Government will not allow it to avail itself of British intervention, though, judging from the temper of the Arabs towards us, and especially towards Colonel Kemball, the British resident at Bagdad, there is the strongest reason to believe that it might be successfully employed for the restoration of order. Indeed, there can be little doubt that the Turkish authorities are aware how speedily, if permitted, we could prevail upon the Arabs to return to their allegiance; but a natural, though blameable, pride leads them to allow the revolt to continue rather than acknowledge their own weakness by accepting assistance.

However, the political state of the country is not the only bar which at present exists to the completion of this part of the telegraphic route to Europe. The work has been so long delayed on that account, that the unhealthy season has set in, and till October or November Europeans will be unable to remain in the neighbourhood of the marshes which lie about the region where it has to be carried on. Till, then, this part of the line has been completed, some means other than electricity must be employed to convey messages across the space between Medina and Diwaniyeh; and

an attempt is being made to do so by *cossids*, or mounted messengers, selected from the inhabitants of the districts through which they have to travel; but it is doubtful whether the country is not too unsettled even for this plan to work successfully; so that the only means which can be confidently relied upon are the river steamers which run between Bagdad and Bussorah, and of which there are now five—two belonging to the Bombay Government, two to the Turkish Government, and one to an English mercantile house (Messrs. Lynch & Co.) The boats can perform the journey down stream in from two and a half to three days, from five to six days being occupied in returning to Bagdad. But unfortunately, even when a message has reached Bagdad, it has not got over all the difficulties which may interrupt its progress; for the Turkish lines between that city and Constantinople are so wretchedly constructed and looked after, that breaks-down are almost as frequent as between Bombay and Kurrachee, while, even if the line happens to be in good order, there is no certainty that English messages will be transmitted in an intelligible language, for the Turks insist on having all messages sent through in Turkish, so that frequently, when re-translated, they bear as much resemblance to their originals as do proverbs in Captain Cuttle's mouth to theirs. So great, indeed, are these evils—the faulty construction of the Turkish lines, and the faulty transmission of messages along them—that when at Bagdad Colonel Stewart determined, after consultation with Colonel Kemball, that a British officer ought to inspect the whole arrangements between Bagdad and Constantinople, and having obtained the permission of the Turkish Government for its being done, he requested Lieutenant-Colonel Frederic Goldsmid to undertake the journey, accompanied by a staff of electricians and others, to assist him in his inquiries with their technical information. We believe that Colonel Goldsmid will remain at Constantinople till Colonel Stewart himself arrives there viâ Aden and Alexandria, when, guided by the information collected by Colonel Goldsmid, the British Ambassador will endeavour to urge upon the Turks all the improvements necessary in their telegraphic system, and will also, we trust, secure the introduction of English signallers for English messages.

We referred above to the disgraceful failures in the line of telegraph between Bombay and Kurrachee, an efficient condition of which can scarcely be counted upon for two consecutive months. At this very moment it is broken down, and messages from this to Kurrachee have actually to go round by Lahore. We are assured by those well qualified to offer an opinion, that no insuperable, or even very unusual, difficulties are the cause of this; but that it results almost solely from the obstinacy of those who insist in refusing to apply to Indian telegraphs the improvements which are being daily made in this almost infant branch of practical science. What would be thought of the railway company which should insist on attempting to carry on the traffic of their lines with engines made after the pattern of Robert Stephenson's "Experiment"? Those who are responsible for the faulty condition of the line to which we are referring may thank their stars that the Turks are as dilatory and careless to improve as themselves, for if the Turkish line had been opened, and messages had come, as they might have done, from England to Kurrachee in forty-eight hours, and had then been delayed five days between Kurrachee and Bombay—a distance of less than 500 miles—the storm of indignation would have been too great even for their callous indifference. They have now a respite of nearly six months; let them see that they employ it well. We may be compelled to put up with inefficiency in lines passing through foreign states, but we must have the highest possible efficiency in those under our own immediate control. If one man cannot do what is required, another can, as we see in the masterly manner in which the Persian Gulf submarine line has been completed.

But to return to the difficulties of completing the communication between the Persian Gulf and Bagdad, we are glad to say that we shall very shortly be able to avail ourselves of another route than that through Mesopotamia. Thanks to the untiring energy of Captain Champain, R.E. (a kindred spirit and an intimate friend of Colonel Stewart), and to the labours of Colonel Lewis Pelly, the British Resident at Bushire (who is now in Bombay), the Persian lines are nearly completed, and may be expected to be in working order within three months. Messages will then leave the submarine cable at Bushire, pass along the Persian line to Teheran, and thence to Bagdad; or if the line between Teheran and Tabreez is open first, they will enter Europe by that route.

Thus we may count with certainty on rapid communication between the east and west within three months; and we have the satisfaction of knowing that if other nations who are interested had worked as hard as we—if they had possessed Stewarts and Brights, Champains and Webbs—it would have existed ere this. We hope a discerning public will not allow those who have worked so hard and so well on its behalf, to go unrewarded with the thanks and credit to which they are so justly entitled, because circumstances entirely beyond their control prevent for a time the full benefit of their labours being experienced. The *éclat* with which the opening of the line might have been anticipated to take place is, of course, altogether wanting now, but the solid advantages of Colonel Stewart's labours can be doubted by none, and will grow and increase day by day. As a soldier, if he be called to command, he can never achieve anything for which he will more heartily deserve the thanks of Government and the public, than for the leading part he has taken in the great work of laying the Indo-European telegraph cable.—*The Times of India, May* 16.

THE AMERICAN COMMISSIONER ON THE POLICY OF PATENTS.

(Continued from page 285.)

ANOTHER class of inventions benefit the community, not by diminishing the price of goods for which there is already a public demand, as in the case just cited, but by producing and introducing labour-saving contrivances which the people must be taught to appreciate and use. Such are the inventions of labour-saving agricultural implements, which within the last twenty years have aided so materially in developing the resources of the country. The inventors and manufacturers of these machines, although prompted by a selfish, but at the same time intelligent interest, have been more truly and effectually the instructors of the people than all the agricultural colleges in the land. The protection which the patent affords is not only the cause in a majority of instances of an invention being made, but it is positively the cause why it is introduced and received. Losing sight of this practical truth, the Government of Canada prohibited Americans from obtaining patents in that province, mainly for the reason that they could obtain the benefit of our inventions without paying for them. The result has been that, as it was for no one's interest to instruct the Canadians in the new mechanical arts of agriculture, they have plodded along with the old tools, and have been benefited by none of the inventions which have stimulated the agriculture of the neighbouring States.

In this country, in consequence of the protection which the patent laws afford, the inventors have found a ready sale of good inventions to capitalists and manufacturers who possessed the capital required to put the inventions into practical form. It is to those manufacturers that the introduction of the seeding, harvesting, and mowing machines, threshers, cultivators, &c., is immediately due. With a single eye to commercial results, they sent their agents through the rich agricultural districts, principally of the west, to exhibit the new machines and teach their operation. The agents convinced the farmers that the saving in the gathering of one year's crop would reimburse the cost of the machines, and readily made sales upon the understanding that the notes given in payment for the purchase should be paid out of the proceeds of the crop gathered by their use. The unparalleled rapidity with which the labour-saving machinery of the farm has been introduced throughout the west, in contrast with the proverbial slowness of the farmers of former times in adopting new improvements, must be attributed to the system I have just described.

We can hardly over-estimate the benefit which the country has derived from these inventions, whose origin and introduction can be so clearly traced to the stimulus and protection by patents.

It is stated by Mr. Kennedy in the census report for 1860 that a threshing machine in Ohio, worked by three men, with some assistance from the farm hands, did the work of 70 flails; and that 30 steam threshers only were required to prepare for market the wheat crop of two counties in Ohio, which would have required the labour of 40,000 men. It is estimated that a single reaping machine effects the saving of the labour of five men. With a good reaping machine ten men will cut, bind, and stack and house from ten to twelve acres per day, or 200 acres in a single season—a task which would have required without machines the labour of fifteen men for its accomplishment. From reliable returns it is shown that 40,000 reapers have been manufactured and sold within the last year; and it is estimated by the manufacturers that over 90,000 will be required to meet the demand for the next year. They will effect the saving of the labour of 450,000 men. The quantity of wheat grown in all the States and territories in the year 1849 was 100,485,944 bushels. The quantity grown in 1859 was 171,183,381 bushels—an increase of nearly 70 per cent., or about double the increase of population in the same period.

It has been remarked that just before the commencement of the present war there was throughout the whole north, from no apparent cause, but, as it seemed, by an inspiration of Providence, a revival of a military enthusiasm which had slumbered for years. Without any concert, military organizations sprang up in every northern State, and at the sound of the first gun at Sumter, regiments, fully armed and equipped, were ready to rush to the capital. It is no less remarkable that the inventive genius of the nation within the last few years had taken a direction which has prepared the nation for the enormous demands upon her men and treasures. In consequence of this influence, the productive energy of the country has not been slackened, yet a million of men could be spared to fight our battles. And thus to each call from our great leader the people have been able to respond—

> "We are coming, Father Abraham,
> Six hundred thousand more!"

The war, instead of checking, has stimulated our creative power in every branch of industry.

Within the last year there have been patented 240 inventions in implements of war, but during that period there have been patented 490 inventions of agricultural implements. And although the happy time foretold by prophecy has not yet come, when the nation shall know war no more, the sword and the spear still yield to the ploughshare and pruning-hook, and the arts of peace hold supremacy over the arts of war.

The next question which I propose to discuss is the comparison of our

own system of patents with those of the great industrial nations. Our patent system is founded mainly upon the statute of 1836, framed under the advice of the most experienced lawyers of the period, but carried through by the energy and wisdom of a distinguished senator of Maine, Mr. Ruggles, who deserves the grateful acknowledgments of the country for securing the passage of an act which has proved one of the most beneficial in our legislative history. The characteristic feature of our patent policy is the system of examination as to the novelty of inventions conducted by the Commissioner of Patents through an examining corps, selected for their special accomplishment in the arts which it is their duty to examine. No system of examination like our own exists in Europe, except to a very limited extent. I have before me a synopsis of the patent laws of nearly all the countries in Europe. In Great Britain, France, Austria, Belgium, Spain, the Roman States, Sardinia, and the Sicilies and Saxony, there is no examination as to novelty. In Prussia, Russia, the Netherlands, Hanover, and Bavaria there is an examination by learned societies and commercial boards, instituted mainly for other purposes, but the whole number of patents granted in the last-named countries in 1858 was only 173; while in the first-named countries in the same year there were issued 10,297 patents. So that, considering the number of patents issued, our own peculiar system stands comparatively alone among those of all civilized nations. But before proceeding to a consideration of our own system, I will state the principal features of the present patent law in Great Britain, which are of more interest to American inventors than those of any other country. These are well stated in a sensible speech made by Sir Hugh Cairns in the House of Commons in May, 1862, whose language I shall use with some abbreviations. The act of 1852 completely altered the system of patents which had previously prevailed. In the first place, before 1852 there was no means by which a person, who supposed he had arrived at an invention, could obtain temporary protection during the time that he was endeavouring to perfect it by experiments; and while making the experiments, there was the danger of their publication, and thus preventing the obtaining of any patent at all. In 1852 the legislature provided that, upon an inventor lodging a description of his invention, he should have a provisional protection for six months. The second change was in reference to the publication of specifications. Up to 1852 the specifications were kept in writing in certain very obscure offices in London, and were virtually inaccessible to the manufacturers of the kingdom. The Act of 1852 provided that all specifications should be printed and sold at a moderate price. A mode of payment entirely novel was originated in 1852. An inventor suing for a patent pays £5 on lodging the provisional specification, and he pays nothing more for six months; at the end of six months, if he wishes to obtain a grant, he pays a sum of £20, and he pays nothing more for three years; during the three years he is able to consider whether the patent is worth any further outlay, and if so, a payment of £50 carries him on for seven years; during the seven years he has the opportunity of considering again whether the patent is worth any further outlay; and if at the end of that time he wishes to be further protected for fourteen years, he has to make a final payment of £100; the total payment is, therefore, £175. And it is held that the payment being made by instalments, and increasing only as the profits of the invention might be supposed to increase, it is hardly irksome in any degree to the patentee—a view, I may remark, by no means supported by others in England who have discussed this feature of the present law. The honourable member inquires what had been the consequence of the change of the law in the increase of the number of patents, and the results of his inquiries remarkably illustrate the benefits of a liberal legislation. Twenty years before the Act was passed, in 1833, the number of patents was 108. In 1851, the year before the alteration of the laws, the number of patents was 455. In 1852-53, after the new Act came into operation, the number of provisional protections for inventions was 3,260, out of which 2,050 patents were actually sealed.

These changes, although far from realizing the demands of the inventors of Great Britain, were vast improvements upon the laws existing previous to that time. Under the old law the process of an application for a patent, as stated in the London *Quarterly Review*, was required to pass through no less than nine stages and seven distinct offices situated in different places. Indeed, the object of sending the application through one of these offices was openly stated in the statute of Henry VIII., c. 11, "that the clerks should not by any manner of means be defeated of any part or portion of their fees." If the letters patent were required to extend to Scotland and Ireland, as well as to England, all the proceedings had to be gone through separately in each of the three cases. Thus the same patent may be said to have run the gauntlet of twenty-one offices. So heavy were the fees—applied not to the expenses of the patent offices, but mainly to swell the emoluments of the Lord Chancellor, Attorney-General, and other high officers—that the cost of a patent for the United Kingdom could not be estimated at less than £350, while the attendant expenses of preparing the specification, &c., often doubled the amount. It cannot be wondered that Mr. Dickens's poor inventor was forced to complain: "Is it reasonable to make a man feel as if, in inventing an ingenious improvement meant to do good, he has done something wrong? How else can a man feel when he is met with such difficulties at every turn? All inventors taking out a patent *must feel so*. And look at the expense. How hard on me, and how hard on the country, if there is any merit in me (and my invention is took up now, I am thankful to say, and doing well), to put me to all that expense before I can move a finger."

Under the present as well as the old laws, the only investigation which alleged inventions undergo before patents are granted is conducted by the law officers of the Crown. They never inquire into the novelty of the invention. All that they do is to see that the alleged inventor describes in a clear and intelligible manner what he claims as his invention, so that he may not add to or take from it.

(To be continued.)

CORRESPONDENCE.

JOINTS IN SUBMARINE CABLES.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—In your last week's number you make reference to some testings which I have had conducted on my submarine telegraph cable under a pressure of 6,000 lbs. (not 6,700) per square inch, and which, as you truly state, gave the most satisfactory results. Permit me, however, to draw your attention to the fact that the core was not "newly-designed," but a length measuring 1,686 yards, of a similar construction to some lengths tested by Mr. Owen Rowland, in November, 1861. It was taken indiscriminately from twenty miles, and may be considered, both in its insulation and construction, as an ordinary illustration of my manufacture. It contained joints. I have joints that were made years ago, some of which have been kept in salt water, others in fresh water, and others exposed to the action of the atmosphere: they all remain perfect.

Many distinguished engineers, and professors of natural philosophy, have witnessed the manufacture of considerable lengths of my cable, and the making of joints. They have satisfied themselves that by my process the joints, *mechanically considered*, cease to exist both in the india-rubber and in the vulcanized exterior, and also that no defect or change can be discovered, electrically or otherwise, in lengths (with and without joints) which have been made upwards of four years. The joints, in fact, test as perfectly as any other part of the insulation, and are as durable. Reports have been obtained from the highest authorities in applied electrical science that two of my cables will convey as many messages across the Atlantic, or any other long length, as three cables of similar size insulated with gutta-percha.—I am, sir, your obedient servant, WILLIAM HOOPER.

7, Pall Mall East, S.W., June 21st, 1864.

[We are glad to learn that Mr. Hooper has succeeded in overcoming an acknowledged mechanical difficulty. The particulars with which we are favoured above, however, leave us completely uninformed as to whether the rubber joints were subjected to the action of a current of electricity for any length of time.—ED. T. J.]

TELEGRAPHIC NEWS.

THE GREAT EASTERN.—This vessel has lately taken on board 3,000 tons of coal, and will shortly leave Liverpool for Sheerness or Deptford, where she will be fitted with water tanks to receive the Atlantic telegraph cable now in course of construction at the works of Messrs. Glass, Elliot, & Co.

RUSSO-PERSIAN TELEGRAPHS.—It appears that, by virtue of a convention recently entered into between Russia and Persia, electric communication is now being continuously carried on between the two countries, by the way of Tiflis.

TELEGRAPHY IN VANCOUVER'S ISLAND.—We (*Weekly British Colonist*) learn from Mr. Strong, a gentleman connected with the State Telegraph Company, that Mr. Superintendent Haynes was about to explore the country between Portland and Puget Sound, with a view to ascertaining the best route for the wires. The work is to be commenced without delay.

MALTA AND ALEXANDRIA TELEGRAPH.—We are enabled to see the progress and commercial value of this important line of communication by a small Parliamentary paper just issued on the motion of Mr. Crawford, M.P. for the City of London. Messrs. Glass, Elliot, & Co., the contractors, entered upon the lease of the line in November, 1861, and up to the end of that year they sent 27 Government messages, and various other local and through telegrams to the number of 1,615, producing a revenue of £8,142 15s. In 1862 business went on at a thriving pace; Government sent 806 official messages, and the public upwards of 19,000. The income was thus raised to £38,380 7s. The year 1863 brought a total of 28,067 telegrams, producing a revenue of £52,142.

THE TELEGRAPH BETWEEN GLASGOW AND ROSENEATH, &c.—Messrs. Reid Brothers are at present engaged in erecting a line of telegraph from Glasgow to the Mull of Cantyne (this important line will include the Northern Light Commissioners' stations of Cantyne, Pladda, and Cumbrae lighthouses) for the receipt and transmission of shipping intelligence along this dangerous coast, with a telegraph station at Lamlash Harbour, where the steam tugs are in readiness to render assistance to vessels when required. This line will open up telegraphic communication between Glasgow, Campbelton, Rothsay, Greenock, Inverary, and Ardrishaig, and between Glasgow and the watering-places on the north bank of the Clyde, such as Dunvon, Mellan, Shone, Kilcreggan, Roseneath, &c.

PROGRESS OF TELEGRAPHY.—The large and extensive manufactory of Messrs. De la Rue, in Bunhill-row, has been fitted up, on the plan of Mr. C. V. Walker by Reid Brothers, of Wharf-road, City-road, with a perfect system of electrical apparatus for connecting the various rooms in the establishment. There is in the arrangement fifty-nine bells, thirty-eight ringing keys, and several galvanometers. The object to be obtained is, that from the central office the manager or foreman of each separate room can be summoned at pleasure to receive instructions from the principal. The bells in each room also give notice to commence, meal hours, and leaving off time. The whole is in the most efficient and perfect working order, and saves a vast amount of time and labour. The clock is regulated by the time from the Greenwich Observatory, and is under the supervision of C. V. Walker, Esq.

BRITISH AND IRISH MAGNETIC TELEGRAPH COMPANY.—The annual fête of the London employés belonging to the above company took place on Saturday last, June the 18th, and proved to be a most attractive réunion. The party (consisting of over forty, including wives and sweethearts) proceeded by train to Sydenham to witness the handicap announced in our columns of February the 20th. After a most exciting race between eight competitors, the final contest was left to Messrs. Wright, Manning, Wild, and Ross; the former being declared the winner by a yard, the others coming in in the order named. The severe struggle at the finish may be judged when we say that barely four yards separated the four above-named gentlemen. The pleasure-seekers then adjourned to the far-famed Anerley Gardens, where, a sumptuous repast being provided by Mr. Hinton, all refreshed themselves to their heart's content, and prepared to join in the amusements provided at this rural spot, viz., boating, swinging, the intricacies of the maze, &c.; but when the splendid band struck up a polka a rush was instantly made to the platform and the light fantastic toes quickly went to work. After a few dances, another move was made to a room specially provided for the occasion, where, Mr. J. C. Newbury being called to the chair, the usual loyal toasts were given, and the prize, consisting of a handsome electro-silver cup, presented by the clerks in charge, was handed to the winner of the handicap, whose health was drank in a bumper of champagne, amid uproarious cheers for "auld Scotland." The other toasts which followed were "Success to the Magnetic Company," coupled with the name of Mr. Edward B. Bright; "The Visitors;" "The Ladies;" and "The Chairman," in whose praise a capital poetic effusion by Mr. J. Brown was read by Mr. J. W. Manning, vice-chairman. An extempore "Song of Events" in connection with the Central Station during 1863-4, was given by Mr. C. Desmond, a retired telegraphist, and was cheered to the echo at several points. A railway-crushing return to town brought this very pleasant Magnetic Derby-day to a successful conclusion, every one having thoroughly enjoyed themselves. In conclusion we may add that the handicap prize is a *Challenge Cup*, the present winner having to hold it against all comers up to December 31st; we shall therefore have to record several contests for this beautiful trophy.

SILVER'S INDIA-RUBBER WORKS AND TELEGRAPH CABLE COMPANY, LIMITED.—Some very important alterations have been proposed in the above company, as will be seen on reference to our advertising columns. The following circular has been sent to the shareholders, with notice that a series of resolutions will be submitted at an Extraordinary General Meeting to be held at the London Tavern, Bishopsgate-street, E.C., on Thursday, the 30th June:—"38, Broad-street-buildings, London, 20th June, 1864.—Dear Sir,—In explanation of the accompanying notice it may be desirable to remind you that one of the main objects of this company was to add to the established manufacture of india-rubber, and the opening one of balata, that of gutta-percha; and I am now desired by the directors to acquaint you that they have succeeded in forming a most desirable connexion for that purpose. Having learned that a new company, strongly backed, was in process of formation for carrying on the manufacture of gutta-percha on a large scale, your directors placed themselves in communication with the gentlemen with whom the project had originated, and having satisfied them of the ample accommodation that would be furnished at Silvertown for the necessary works, they have entered into an arrangement for an amalgamation of the two undertakings. You are no doubt aware that the india-rubber and gutta-percha manufactures of this country have hitherto been to a great extent excluded from France and Belgium, where protective duties have counter-balanced the inferiority of quality which results from inefficient management, and you will readily recognize the enhanced value that would attach to the foreign factories if their cheap labour were brought under the control of the skill and experience gained in English works. The inquiries instituted by your directors have resulted in a contract for the purchase of three of the most important of the French and Belgian factories, whose valuable patents render the acquisition of these works indispensable to the carrying out of the objects of the company with reference to the continental business. In view of the extent of operations at home and abroad now contemplated by the company, it was considered requisite to double the nominal capital, at the same time adhering to the former policy of issuing one-half only in the first instance; and this half it is proposed to dispose of as follows:—The promoters of the New Gutta-Percha Company, who, with their friends, contemplated subscribing a large capital for their original object, have now the option of taking a considerable proportion of the £250,000 stock which it is now proposed to issue, and a similar option is given to French subscribers on behalf of the continental purchases, which involve an outlay of some £60,000. Any balance will be offered, pro râta, to the existing shareholders. The above arrangements include the introduction of John Harvey, Esq., and George Henderson, Esq., of 7, Mincing-lane, as directors of the company, and of two gentlemen of similar standing in France. The directors have also pleasure in announcing that they have secured the services of Messrs. Charles and Walter Hancock in the management of the balata and gutta-percha department of the manufacture.—I am, sir, yours obediently, JUSTINIAN PELLY, Secretary."

MISCELLANEA.

REPETITION OF WORDS.—A number of Pitman's *Reporter* calculates the proportionate use of words in 30,000 to be as follows:—

The	1727	is	366	be	278	have	193
and	1221	it	353	as	231	which	193
of	1153	his	288	he	228	all	184
to	864	with	278	but	202	from	184
in	581	for	270	are	198	your	177
that	416	you	265	not	195	or	164

This, we, they, may, will, our, him, on, their, at, more, what, me, them, who, &c., taper down from 150 to 100.

JOULE'S NEW SENSITIVE THERMOMETER.—At a recent meeting of the Manchester Philosophical Society, Dr. Joule exhibited an exquisitely sensitive air thermometer, capable of being affected by the $\frac{1}{1000}$ of a centigrade degree of heat. The construction is thus described:—"A glass vessel in the shape of a tube, two feet long by four inches in diameter, is divided longitudinally by a blackened pasteboard diaphragm, leaving spaces at the top and bottom, each a little over an inch. In the top space, a piece of magnetized sewing needle, furnished with a glass index, is suspended by a single filament of silk. It is evident that the arrangement is similar to that of a bratticed coal-pit shaft, and that the slightest excess of temperature on one side over that on the other must occasion a circulation of air, which will ascend on the heated side, and, after passing across the fine glass index, descend on the other side. It is also evident that the sensibility of the instrument may be increased to any required extent, by diminishing the directive force of the magnetic needle. I purpose to make several improvements in my present instrument; but in its present condition, the heat radiated by a small pan, containing a pint of water heated 30°, is quite perceptible at a distance of three yards. A further proof of the extreme sensibility of the instrument is obtained from the fact that it is able to detect the heat radiated by the moon. A beam of moonlight was admitted through a slit in the shutter. As the moon (nearly full) travelled from left to right, the beam passed gradually across the instrument, causing the index to be deflected several degrees, first to the left and then to the right. The effect showed, according to a very rough estimate, that the air in the instrument must have been heated by the moon's rays a few ten-thousandths of a degree, or by a quantity, no doubt the equivalent of the light absorbed by the blackened surface, on which the rays fell."

THE MOST RECENT SPECTRUM DISCOVERIES.—The following is an abstract of a lecture on the above subject, delivered before the Royal Institution, by Professor Miller, F.R.S.:—"Among the rays emitted by the sun, there were three kinds interesting as endowed with special action—those which conveyed heat, light, and chemical action. With heat he should have but little to do on this occasion; about light he had something to say, but he was now principally concerned with the rays which manifested themselves by producing chemical action. It was well known that transparent substances did not transmit all these rays with equal facility. Glass was only imperfectly transparent to the chemically active rays, which were found in the most refrangible rays of the spectrum, heat rays being in the least refrangible portion, and light occupying the middle place. It had been found that rock-crystal was one of the few substances which perfectly transmitted those highly refrangible rays which glass absorbed. The professor then showed that some kinds of light were without chemical action, the light from a mixed air-gas flame possessing scarcely any, while that from an ordinary gas-flame did possess a little. The oxy-hydrogen flame, while attended with intense heat, was endowed with very little chemical action. A prepared collodion plate exposed to this light for twenty seconds gave a very faint picture. But when the flame was thrown on lime, although the temperature was lower, the light had sufficient chemical activity to produce a strong picture on a similarly prepared plate, exposed for the same time. In the case of the chemically acting ray, the intensity, number, and position of the lines on the spectrum had been found to vary with the source of light. The most remarkable illustration of this was the different spectra produced by the electric spark of an induction coil between poles of different metals, and projected upon a photographic plate. The spectrum produced by the spark from silver poles, for example, was found to be three times the length of the whole of the solar spectrum transmitted by quartz. In order to obtain views of this invisible spectrum, it was necessary to transmit the rays through a medium more transparent to chemical rays than glass, which, it had been said, was opaque to the higher rays of this kind, and various experiments had been made to ascertain what substance allowed them to pass most freely."

Magnesium.—In the *Proceedings of the Royal Society*, No. 63, are reported some researches of Dr. T. Phipson on this metal, now becoming so interesting in relation to its illuminating properties. He states that magnesium is capable of reducing silicic acid at a high temperature, which the alkaline metals, sodium, and potassium, cannot do, as they volatilize before the crucible attains the proper heat. It decomposes carbonic acid from dry carbonate of soda, and it precipitates nearly all the metals from their neutral solutions. Unlike zinc, it will not unite with mercury at the ordinary temperature of the air. With platinum, according to M. Sonstadt, it forms a fusible alloy; and it is probable that an alloy of copper and magnesium would differ from brass not only in lightness, but by being able to decompose water at the ordinary temperature with more or less rapidity. This last effect is also produced by combination of sodium and potassium, which are very malleable alloys. Magnesium will be found a useful metal whenever tenacity and lightness are required, and where tarnish is of no consequence. It is especially valuable in the laboratory for effecting decomposition, which sodium and potassium cannot effect on account of their greater volatility.

The Voltaic Battery.—Faraday has shown that in a voltaic battery the chemical action in each cell is exactly proportional to the quantity of electricity flowing through it. Now, every part of a circuit (including, of course, the battery), whatever be its form, nature, or resistance, is traversed in a given time by equal quantities of electricity; just as in a river the same quantity of water passes any given part of the channel each minute, whether the stream be narrow or broad, shallow or deep, because each part is supplied by that which precedes it, and in the like manner supplies the succeeding length. From this cause the chemical action in each cell is equal where there is no waste from local action (36), an equal quantity of sulphate of copper is decomposed, and an equal weight of zinc dissolved, in each cell in the series. That is to say, if in one cell of a series of 100 one ounce of sulphate of copper be decomposed, exactly one ounce (neither more nor less) will be decomposed in each of the other 99 (it matters not whether these cells are active, as in a battery, or not); therefore, to circulate a given quantity of electricity, an equal amount of sulphate of copper is consumed in every cell used to circulate it. For every 32 lbs. of metallic zinc dissolved, 124 lbs. of sulphate of copper will be decomposed, and about 32 lbs. of metallic copper deposited upon the copper plates.—*Mr. R. S. Culley's Handbook.*

The Divisibility of Matter.—What the real size of ultimate particles may be we have no means of determining, although, as will be seen hereafter, there are strong grounds for believing that the divisibility of matter, extreme as it is, has its assigned and definite limits. Experience, however, shows that whatever be the form of matter selected for our experiments, that divisibility may be manifested to an extent which transcends our powers of conception. The divisibility of gold is often given in illustration of this point. In the ordinary process of making gold-leaf, a single grain of gold is hammered out until it covers a square space seven inches in the side. Each square inch of this may be cut into 100 strips, and each strip into 100 pieces, each of which is distinctly visible to the unaided eye. A single grain of gold may thus, by mechanical means, be subdivided into $49 \times 100 \times 100 = 490{,}000$ visible pieces. But this is not all; if attached to a piece of glass, this gold-leaf may be subdivided still further; 10,000 parallel lines may be ruled in the space of one single inch, so that a square inch of gold-leaf, weighing $\frac{1}{49}$th of a grain, may be cut into 10,000 times 10,000 or 100,000,000 pieces, or an entire grain into 4,900,000,000 fragments—each of which is visible by means of the microscope. Yet we are quite sure that we have not even approached the possible limits of subdivision, because, in coating silver wire, the covering of gold is far thinner than the gold-leaf originally attached to it, since in drawing down the gilt wire the gold continues to become thinner and thinner each time, in proportion as the silver wire itself is reduced in thickness.—*Miller.*

PATENTS.

APPLICATIONS FOR LETTERS PATENT.

1496. T. J. Hughes, an improved composition to be used for coating and insulating.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

1340. T. W. Smith, improvements in "tell-tales," or apparatus for registering or indicating the hour at which any desired apartment or spot has been visited.

NOTICES TO PROCEED.

1345. P. Deeley, a new or improved machine for testing the strength of wire.

PATENTS SEALED.

3290. H. Caunter, improvements in the manufacture of lubricating matter or composition.

PATENTS ON WHICH THE STAMP DUTY OF FIFTY POUNDS HAS BEEN PAID, AND DATES OF THEIR PRODUCTION FOR CERTIFICATE.

1539. F. Potts, certain improvements in the manufacture of metallic posts for supporting telegraph wires, and which said improvements are also applicable for other purposes.—15th June, 1861.

1580. J. F. Williams, improvements in compounds of india-rubber and gutta-percha with other substances.—19th June, 1861.

PRICES CURRENT OF INSULATING MATERIAL.

Gutta Percha, as imported.

TO CORRESPONDENTS.

Arrangements have been made with contributors in all parts of the world, whereby we shall be able to lay before our readers the most reliable information concerning telegraphy on the continent and in America.

As information respecting Improvements, Extension of Lines, and Progress of New Undertakings will at all times be most acceptable, we hope that our readers will kindly render us assistance in our efforts to establish a Journal worthy in all respects of the great interest it seeks to represent, by furnishing us with brief notices of events and occurrences in connection with Telegraphy.

Communications intended for publication must be authenticated by the names and addresses of the writers; not necessarily for insertion.

Letters relating to Advertisements are to be addressed to the Publishers. All other letters and communications to be addressed to the Editor of the *Telegraphic Journal*, 5, Suffolk-lane, Cannon-street, London, E.C.

The *Telegraphic Journal* can be had of Messrs. Smith & Co., Strand; Messrs. Dawson & Co., Cannon-street, E.C.; Messrs. Kent & Co., Paternoster-row, London. Messrs. Heywood & Co., Manchester; at the various railway stations; and of all news-agents, &c., &c.; or it can be supplied, if preferred, direct from the Office on the following terms:—

	s.	d.
Quarterly	4	4
Half-yearly	8	8
Yearly	17	4

TO ADVERTISERS.

The *Telegraphic Journal* is the most effective medium for inventors, patentees, contractors, manufacturers of insulating materials and electrical apparatus to submit their various specialities to the consideration of secretaries and managers of telegraph or railway companies, and other persons engaged in electrical and telegraphic pursuits.

Advertisements must be delivered to ensure insertion before Seven O'Clock on Thursday evening in each week. The charges for Advertisements are—

	£.	s.	d.
Whole page	4	4	0
Half ditto	2	10	0
Quarter ditto	1	7	6
Four lines and under (single column)	0	3	0

Single Advertisements from the country must be accompanied with stamps in payment.

THE

TELEGRAPHIC JOURNAL:

A

WEEKLY RECORD OF ELECTRICAL AND SCIENTIFIC PROGRESS.

VOLUME II.

London:

TRUSCOTT, SON, & SIMMONS,

SUFFOLK LANE, CANNON STREET, E.C.

1864.

LONDON:
Printed by Truscott, Son, & Simmons,
Suffolk Lane, City.

TO OUR READERS.

When the *Telegraphic Journal* made its *début*, we stated our objects and solicited support. Now, on the occasion of publishing the last number of the second volume, we purpose addressing a few observations to our readers on the present aspect of electrical science and telegraphic art, and to show that our efforts to establish an organ for the diffusion of knowledge on these subjects have not met with the countenance and patronage we had anticipated.

It is but a short time since we directed attention to a Report on Electrical Standards, prepared under the auspices of the British Association for the Advancement of Science, by a committee of the foremost men engaged in scientific pursuits. We freely criticised this document in a recent issue, and, in dismissing all thought of arriving at any satisfactory conclusions from a further perusal of the anomalies of the "Thirteen," whose prestige led us to expect better things from them, we are constrained to confess that, though avowedly defining and explaining standards for electrical measurements in a very elaborate manner, this addition to the records of the British Association, renders "confusion worse confounded." The annals of literature have not been considerably enriched of late by contributions of electrical lore, yet great advances have been made in the application of the subtle fluid to useful purposes. Among the most conspicuous improvements in electrical apparatus is Mr. J. B. Thompson's induction machine, an instrument whereby currents of electricity moving in one direction, of any required electro-motive force, may be obtained from a battery of small electro-motive power. The particular uses of this machine are for telegraphing, submarine cable testing, and electro-plating; it is also invaluable for the production of the electric light, and for coating the entire iron exterior of ships with copper. Many other ingenious adaptations of electricity have come under our notice, but we cannot proceed to enumerate them in this place.

The rapid extension of the business of electric telegraphing in all parts of the world is the best evidence of its utility and importance. The idea of Puck is in course of realization. Not only do we join house to house, and town to town, but from island to continent, from continent to far distant empires, through deep seas and unfathomed oceans do we stretch our cables, in order to facilitate the means of speedy communication. The much vexed question as to the practicability of laying and then signalling through long lengths of insulated wire submerged in great depths has been definitely settled. The Persian Gulf Telegraph is no longer an experiment, but may be pronounced *un fait accompli*. This great triumph leads us to hope that success will attend the renewed attempt which will be made in the spring of the ensuing year to permanently unite England with America. The work of manufacturing the cable for this purpose is progressing rapidly, and there is every prospect of the Atlantic Telegraph Company being able to restore the public confidence in submarine telegraphy, so terribly shaken by the disaster of 1858. Of the projects in contemplation, perhaps the boldest in conception and design is that for linking India, China, and Australia by a chain of electric telegraphs. Not only does the eminent engineer, Sir Charles Bright, certify to the feasibility of this scheme, but he expresses his conviction that the necessary works for effecting this object may be completed in a few years.

Having thus briefly alluded to the condition of electrical science, and the state of telegraphic art, we desire to communicate to our subscribers a determination to which we have been impelled by a combination of circumstances which it would be unwise to ignore. We acknowledge with thankfulness the aid rendered by Admiral FitzRoy, Mr. W. H. Preece, Mr. R. S. Culley, and other gentlemen (whose services are deserving of special recognition, but whose names we are not at liberty to proclaim), in supplying information, and otherwise contributing to the usefulness of the *Telegraphic Journal;* but, inexplicable as it may appear, it is nevertheless true, that we have never received the countenance of the body of practical telegraphers. It has been our duty to chronicle from time to time the researches of investigators, to describe new inventions, to keep a watchful guard over the interests of shareholders in telegraph companies, and to promote the welfare of the persons employed in telegraph offices. As to the manner in which we have performed these trusts, let our readers testify. At a great pecuniary sacrifice we have sustained the *Telegraphic Journal* now twelve months, striving, with the resources at command, to make it worthy the perusal of the man of science, and interesting to the humble telegraph operator. The conscientiousness of having performed a public service will enable us to bear the loss already incurred by our venture; but we cannot continue to occupy the position of "guide, philosopher, and friend," to telegraphers, under the conditions with which the office is invested. This number will therefore conclude the second volume, and be the last of the *Telegraphic Journal.*

4 & 5, Suffolk Lane, E.C.,
24th December, 1864.

INDEX.

ABRIDGMENTS of specifications relating to electricity and magnetism, their generation and application, 58, 75, 88, 100, 111, 126, 136, 148, 160, 172, 187, 195, 206, 223, 233, 248, 273, 282, 295, 303.

RAILWAY ACCIDENTS.

THE inquest at Egham has closed. The verdict has been given. The driver and his fireman have been convicted of manslaughter, and the London and South-Western Railway Company have been severely condemned for their mismanagement.

No one for a moment will hesitate to coincide with the justness of this verdict, at least as regards the engine-driver. It is impossible to overrate the responsibility that rests upon this class of men: they hold the lives of thousands in their hands. The slightest neglect, the least carelessness drags hundreds into imminent danger. They have signals to guide them, firemen to assist them, guards to check them, and yet cases occur where wild heedlessness and gross inattention leads to frightful suffering and lamentable woe. Where dependence is placed upon human agency, there must be human error. The arrangements of a railway company may be perfect; the signals may be up; danger may be visible; yet a thoughtless driver may dash his train into the midst of peril. Such temerity can only be punished by severity. Take this Egham accident. On a busy racing day, when the line was blocked with trains crammed with pleasure-seeking excursionists, a stupid engineman drives his precious train, at express speed, over a line which he knows only a few minutes previously has been traversed by another heavy burden. He suddenly is warned of danger a-head. The upright semaphore arm, the red flags, the wild gesticulations of a frantic station-master bid him stop, but he has lost all control of his train, he dashes on, and death and frightful sufferings result. The verdict is therefore just as regards this man: he will be tried for manslaughter, and let us hope that he will be punished accordingly. But are the jury right in condemning the arrangements of the railway company? The driver was told not to travel at a greater speed than thirty miles an hour—he went fifty. He was told when he saw a danger-signal a-head to stop, and proceed gently until he approached the danger—he neglected the signals. Are the railway company responsible for this? The jury say they ought to have had a turntable at Ascot, but would a turntable have prevented the accident? They say there was no communication between the guard and the driver, but would such communication have in any way mitigated the effects of the accident? Not in any way. Communication between guard and driver is found practically useless, and in this particular instance would have been of no avail.

But the jury condemn the company "for not using telegraphic communication from station to station." Here we must pause. Would the proper use of the telegraph on this line have obviated this distressing affair? We unhesitatingly answer *yes*. There are two systems upon which lines of railway are worked: the one is termed the *time*, and the other the *block* system. The *time* system presumes that trains are always to be maintained a certain distance apart by an interval of time. Thus one train is not allowed to pass a station until a previous train has disappeared at least five minutes before it. The *block* system provides that trains shall always be maintained apart by a certain *space* of line. Thus two trains are never allowed to come within two miles of each other. The line is divided into certain spaces of about two miles in length, and no two trains are allowed to be on the same space at the same time. The South-Western Company work their lines on the time system, with what result is shown in this accident. Had they adopted the block system could the accident have happened? Undoubtedly not; for the second train could not have left Virginia Water before the first train had left Egham. They would never have been within two miles of each other. This block system is the only safeguard against collision, and though railway managers object most powerfully to its use, we believe the day not far distant when the legislature will take the matter into their own hands, and compel railway companies, when their traffic amounts to a certain quantity, to work their traffic upon that plan. Government inspectors are ever urging its use upon them, and in this very inquest, Col. Yolland has spoken most strongly upon the point. He said:—"The danger of running trains at intervals can only be obviated by the block system of telegraph." This is the burden of every Government Inspectors' Report. The Brighton Company did not adopt it until they gained bitter experience at Clayton Tunnel. The Midland Company have been strongly urged to carry it out, and have for some time had it under consideration. The Metropolitan line strictly carry it out, and the North London have no difficulty in working their heavy traffic by its means. Other railway companies are gradually adopting it, and the South-Western will now, doubtless, take it into their deepest consideration.

The jury at Egham are undoubtedly justified, to some extent, in animadverting upon the arrangements of the railway company, but we must attribute the whole and sole cause of this frightful accident to the gross negligence of a heedless driver.

ON ENERGY.

Contributed by BLANCO MOUGREVE.

I have just read an article in the *North British Review*, on "Energy." It professes to be a popular exposition of the matter, yet it gives a rather unpleasant sneer at the fine writing of certain popularisers of scientific subjects. It seems to point to one well-known, and whose popular lectures are highly appreciated; but it is a pity that it does not contain at least some of the clearness of those lectures. There is another rather unpleasant thing in the beginning of it, namely, a decrying, I will not say of fellow-labourers, for the writer appears to me to be a dealer in second-hand wares; if he be not, then I am sorry that his article so misrepresents him. The modest Mayer is the person he particularly points at, who has been content to give us what his scientific prevoyance has seen, and what his experiments have proved, and then to retire into the dark. To the writer, theory appears to be nothing, but experiment everything! Yet is not theory of the sight, and experiment of the touch? By that at least you can walk with the head erect; but by this you must grovel and grope your way, and neither the one nor the other alone will ensure your going right. The latter deals with changes of matter: the former with spiritual laws. Together they build up our knowledge: divorced they are nothing, and worse. Did not Mayer see the indestructiblity of force as clearly as that of matter? Was it a vain imagining? I grant that Joule saw and proved somewhat, and that is better no doubt; but did not Newton see that water contained a combustible substance, and that diamond was combustible; but he did not prove these things; yet his scientific intuitions have been held up as something marvellous: and were they not? Certainly! *Malgré toi.*

What we used to call force, is here called energy; it does not much matter which be used so long as we express clearly what we mean.

There is said to be two forms of energy: *potential* and *kenetic* or "static force," and "dynamic force" according to some, or which is perhaps clearer "force in effort" and "force in act;" however, if potential and kenetic energy be adopted by scientific men, well and good.

The first thing that strikes us as of apparent value is the enunciation of the laws that govern energy in all cases. They are three:—1st. *Conservation;* 2nd. *Transformation;* 3rd. *Dissipation.*

1st. "The conservation of energy simply asserts that the whole amount of energy in the universe, or in any limited system, which does not receive energy from without, or part with it to external matter, is invariable."

There is Law the first. I do like a law; it is like firm ground to the sole of one's foot: but I *should* like to understand this one, as the writer meant it; that is, perhaps, hopeless though. However, let me set down what it says to me:—That in every system the energy therein remains invariable, if none be received from without, and none be given out from it to external matter. That is a self-evident proposition if you like, but not much of a law. I think it may be classed with "That which *is*, *is*," and "A thing cannot both *be* and *not be* at the same time." As to the meaning intended, I feel constrained to give it up, and will proceed to

Law 2nd. "The *transformation of energy* is the enunciation of the experimental fact, that, in general, any one form of energy may, by suitable processes, be transformed wholly or in part to an equivalent amount in any other given form. It is subject, however, to limitations which are supplied by the *dissipation* of *energy*."

In the first place, I was not aware that a law was the "enunciation of an experimental fact." I always thought that a law was the embodiment of the generalisation of many series of experimental facts. What is still more astonishing, the same law is said to be subject to limitations. A generalisation subject to limitations! Can it be imagined? I know that some people say that the "exception proves the rule," but as I understand Law, the exception or limitation simply disproves the pretended law. Have nature's laws any exceptions or limitations? But what are our enunciations of laws worth, if they be not the enunciations of nature's laws. They are simply delusions. Let us first strive to find out nature's laws before we pretend to enunciate any.

Third Law. "*The dissipation of energy.* No known natural process is exactly reversible, and whenever an attempt is made to transform and re-transform energy by an imperfect process, part of the energy is necessarily transformed into heat and *dissipated* so as to be incapable of further useful transformation. It therefore follows, that as energy is in a state of transformation, there is a constant degradation of energy to the final unavailable form of uniformly diffused heat, and that this will go on as long as transformations occur, until the whole energy of the universe has taken this final form."

This third law, or limitation to second law, or whatever it may be, is a strange enunciation after the other two strange ones. It leads one almost to ask does the writer mean, firstly, that *energy is indestructible*, and, secondly, that *energy is transformable.* If he does, then energy, under no circumstances, can be destroyed, and if it is transformable, then we should like to know under what conditions. He tells us there are but two forms of energy, *potential* and *kenetic.* But the very essence and nature of energy is to produce change of state or change of place, and it must of necessity be always producing such change or in effort to produce such change; but if in effort only and not in actuality, then it is because there is some equal and opposite energy resisting. This latter is what he calls potential energy, the former kenetic energy. Now clearly it must be under the kenetic form or condition that it is transformable, as it is impossible for transformation to take place when it is in the potential or static condition.

But in which of these forms is it that energy becomes dissipated, or unavailable? Is it the kenetic form? I should think not; for that is *force in act*, which is change, and not dissipation, and is still as available as before though in another form. Still less can it be the potential form; for here we have two opposite forms of force opposing, and waiting for us to upset the balance and utilise them. Coal, and food, and in fact the whole of chemistry, are examples of this, besides man's mechanical contrivancs, and all force in act give examples of the former, but not of dissipation, but change. What then can be the meaning of the dissipation of energy; it is not made clear by the writer, and looks to me somewhat like an impossibility. I will give up the attempt to understand the writer's three fundamental laws, if, indeed, they are understandable at all, and just look at one or two of his "semi-historical cases."

Speaking of the excitation of electricity by the electrophorus —an electrophorus is a cake of resin and a copper disc—he says:—"When *any* two bodies are brought into contact, there is a certain amount of exhaustion of the potential energy of chemical affinity between them, and the equivalent of this is partly at least developed in the new potential form of a separation of the so-called electric fluids."

Now who says that there is chemical affinity between resin and copper? It strikes me that Fownes does not say so, nor any one but our learned author.

I will not attempt to say what is or is not possible, but simply ask, is it proved by an experiment of our author, or any one he knows? If not, I should just remind him of the "famous Tenterden steeple." I can agree at least with the author in his disbelief in the "so-called" electric fluids, seeing that a fluid cannot be simply energy, but must be energy and something more; yet he still goes on talking about the two electricities, as if he believed it all the time. He says:—"We have already noticed that contact of two bodies, such as zinc and copper, developes a constant difference of potential between them. From the explanations subsequently given, with reference to the potential, we see that this is equivalent to saying that at the surface of contact there is perpetually a force tending to separate the two electricities in a direction perpendicular to that surface, while at points ever so little within either of the bodies, there is no such force."

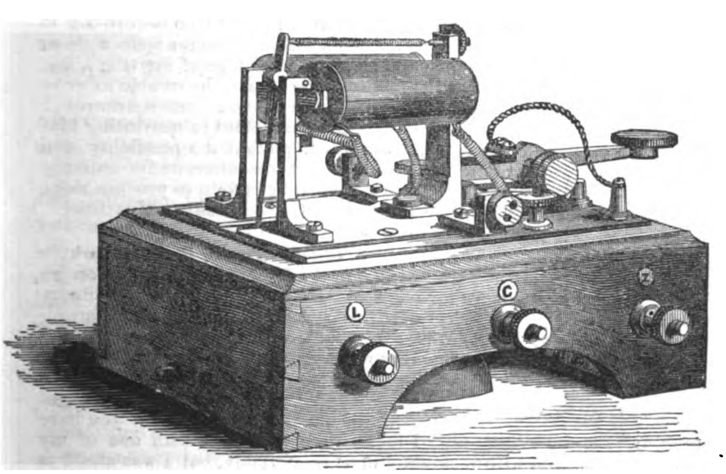
Now, mind you, our author never theorises, but builds everything up on the most rigid experiments, and no doubt in due time he will publish his experiments, upon which all this and much more like it is founded. At any rate he has settled the dispute between the contact and chemical theorists. It is to be hoped that the author is better informed respecting most subjects that he writes about, than he seems to be about Mr. Holmes' magneto-electric machine; he describes it as being formerly at the South Foreland, but does not seem to know that it is now at Dungeness, and he makes the magnets revolve before the spores, which they never did.

It is a pity but that popular writers on scientific subjects would first make themselves masters of the subjects about which they wish to write, not by cram, but really to know what they would say, and then try if they cannot express it simply and clearly, or leave it alone altogether.

Hoping, sir, that if you see fit to publish this, some one competent to handle the interesting subject, about which the writer in the *North British Review* professes to treat, will take it up and give us a thorough exposition of it; and I know of no place so suitable as your journal, as it is mainly concerned about the utilisation of two of the principal forms of force or energy, electricity and magnetism.

RUDALL'S ELECTRIC TRAIN SIGNALLING BELLS ON THE LONDON, CHATHAM, AND DOVER RAILWAY.

THIS bell is decidedly one of the simplest construction, consisting merely of the usual horseshoe electro-magnet, with an armature which is supported on pivots and works to and fro accordingly as it is attracted by the electro-magnet, or acted upon by the adjusted spiral spring. The hammer which strikes the bell underneath the case is attached to the armature by a piece of stout wire about six inches in length. The bell can be rung with the same battery power at a distance ranging from three or four up to ten or twelve miles, which is a great advantage in practice, as it gives the power of cutting out small intermediate stations at night without interfering with the station to station system of signalling which is there carried out between the larger stations. After the line and battery connections are properly made, all that is necessary to transmit a signal from one station to the other is to press the tapper firmly down for about a second, by which means one pole of the battery is brought into contact with the earth, and the other pole with the line. Now as, when the bells are at rest, the line is always in communication with the earth through the electro-magnetic coils, on depressing the tapper at either station, the circuit is completed, the armature attracted by the temporary magnet, and the hammer sharply struck against the bell below.



The system of train signalling by bells of a somewhat similar description to the above has been successfully practised for many years upon the South Eastern Railway, under the superintendence of Mr. C. V. Walker, F.R.S., who originated and introduced it. During the time it has been in operation on the London, Chatham, and Dover Railway, we understand it has been worked with the most satisfactory results.

The system adopted where these bells are used for train signalling is as follows:—

One blow given and acknowledged once, for all up stopping and goods trains *out*—(*i.e.*, about to leave a station.)

One blow given and acknowledged *twice*, for all *up* special, and non-stopping trains, or engines *out*.

Two blows for all *down* stopping and goods train *out*.

Two blows given and acknowledged *twice*, for all *down* special, and non-stopping trains *out*.

Three blows for all trains and engines *in*.

The in-signal not to be given until the station is clear, and ready to receive another train on the same line; and no train or engine to be started from a station until the *in*, or all clear signal, has been received for the preceding train.

Four blows, a special signal at junctions, &c.

Five blows—*Danger Signal*—to stop everything on the line, to be used in all cases of obstruction, shunting, &c.

Three blows given and acknowledged *twice*, the *all clear* signal.

Seven blows, for calling attention to the speaking instrument.

Eight blows, signal to test the bells.

In all the above cases, every signal received is to be immediately acknowledged by repeating back the same number of blows as received; and no signal is to be considered as sent until so acknowledged, after which it is to be booked without delay. These bells are equally adapted for stations where Clerk's block-needle instruments, or other systems requiring a bell in addition, are used. Besides calling attention to the block instruments, &c., they enable the signalmen to indicate the description of train about to start.

Should the bell fail, the above regulations, as to the progress of trains and engines, are to be carried out by means of the speaking instruments; and should telegraphic communication be wholly stopped, the progress of trains and engines must be regulated in strict accordance with the general rules of the Company for working the line by means of the Semaphore danger-signals only, with this addition, that every train and engine must be stopped, and the driver and guards verbally cautioned by the station-master that the preceding train has not been telegraphed "In," and that a good look-out must be kept.

MEMOIRS OF DISTINGUISHED MEN OF SCIENCE OF GREAT BRITAIN, LIVING IN THE YEARS 1807-8.*

By WILLIAM WALKER, Jun.

THIS little handbook was originally intended as a key to a very beautiful historical engraving by Mr. William Walker, assisted by Mr. Zobel, from a design by John Gilbert, of an assemblage of fifty-one eminent men—astronomers, chemists, engineers, electricians, mechanical inventors, and naturalists (many of them still in the land of the living), grouped in the library of the Royal Institution. The memoirs, however, proved so exceedingly attractive that the publishers, having made several additions to the list of England's worthies, have reprinted the volume, which, with the suggestive introduction by Robert Hunt, F.R.S., will be read with interest and profit. The author lays no claim to originality, as most of his subjects have been in their turn "men of mark," but he has most judiciously compiled and arranged a series of pen and ink portraitures of which the nation may well be proud; they are necessarily brief, but the leading features in all the biographies have been concisely wrought, and the volume may be considered a *multum in parvo*. In order to give our readers an idea of the little *brochure* now before us, we will not extract from the author, but give a sketch, as we find it, of one of the pioneers in the art of electro-telegraphy:—

FRANCIS RONALDS, F.R.S.

Francis Ronalds was born in London, in the year 1788. From a very early period in life he devoted himself to the advancement of electrical science, a course he has consistently pursued during a large portion of his life, which has not yet we are glad to be able to state drawn to its close. He is the inventor of an electric telegraph, electrical machine, electrometer, a new mode of electrical insulation, a pendulum doubler, an electric clock, several meteorological and magnetical instruments and other mechanical contrivances. The year 1816, however, marked Mr. Ronalds' great achievement in the advancement of electric telegraphs. During that year he was the first to demonstrate that they could be practically and unerringly applied to the passage of messages through a long distance. Well aware of the difficulties arising from imperfect insulation, which had baffled his predecessors, Mr. Ronalds secured the success of his apparatus both by employing better means of insulation than had hitherto been adopted, and also by making use of a form of apparatus which should of itself be capable of supplying any loss of electricity which might arise from defects in the insulation.† Mr. Ronalds placed his telegraph wire in glass tubes surrounded by wooden troughs lined with pitch, which were placed in a trench dug in his garden at Hammersmith. He also suspended eight miles of wire by silken cords from a wooden frame erected on his lawn, through which he was enabled to successfully pass messages except in wet weather, the cords not being protected from the wet.

Mr. Ronalds' peculiar form of apparatus may be thus briefly described:—At two stations were placed two clocks, with a dial with 20 letters placed on the arbour of the second hand; in front of each of these dials was placed a screen with a small orifice cut in it so that, as the dial revolved, only one letter could be seen at a time. The clocks were made to go *isochronously*, and were started at the same instant with the same letter appearing on the dial through the orifices of each of the screens, both dials, therefore, as they revolved, would of course continue to show similar letters. This formed the readable index of his telegraph; means of communication between the two stations were produced in the following manner:—connected with each end of the telegraph wire, and placed in front of the clocks, were two pith ball electrometers, upon which a constant stream of electricity, produced from an ordinary frictional machine, operated and consequently kept in a state of divergence, except when a letter on the dial was to be denoted; the electricity was then partially discharged by breaking the connection, the pith balls in a measure collapsed, and the distant observer was thereby informed to note down the letter then visible through the orifice on the screen.

* London: E. & F. N. Spon, 16, Bucklersbury.

† This peculiarity of Mr. Ronalds' apparatus is stated in full by Mr. Highton, C.E., in his work on the "Telegraph," page 50. London, John Weale.

In this way letter after letter might be denoted and intelligence of any kind conveyed. All that was absolutely required for the success of Mr. Ronalds' telegraph was, that the clocks should go isochronously *during the time* intelligence was being transmitted, for, by a preconcerted arrangement, both clocks might be easily started at the same letter upon a given signal. The attention of the distant observer was called by the explosion of gas by means of an electric spark. In 1823, Mr. Ronalds published a full description of his telegraph, in a work entitled, "Descriptions of an Electrical Telegraph, and of some other Electrical Apparatus."

In 1825, Mr. Ronalds invented a perspective tracing instrument, to facilitate drawing from nature or from plans and elevations, an account of which he published in 1828, in a work entitled "Mechanical Perspective." With this machine he was enabled some years afterwards (in 1835), assisted by Dr. Blair, to procure exact perspective projections taken from given noted stations, of the Celtic remains at Carnac in Brittany. The result of these researches was published by Mr. Ronalds and Dr. Blair in 1836, and was entitled, "Sketches at Carnac; or, Notes concerning the present state of the Celtic Antiquities in that and some of the adjoining Communes." In connection with this tracing apparatus, he likewise contrived a hexipod staff used for a support, and which has been much employed for the support of instruments requiring great steadiness, such as telescopes, theodolites, cameras, &c. In the year 1843 he became the first and honorary director of the Kew Observatory, and while occupying this office he supplied the observatory with various new contrivances, for which he received a government reward from the special service fund, and a small pension from the civil list. The most considerable of these contrivances were his atmospheric electrical conductor and its appendages, adopted at the Greenwich, the Madrid, and the Bombay magnetic observatories; his photo-barograph, and two photo-thermographs, adopted at the Radcliff observatory, Oxford; his photo-electrograph, and three photo-magnetographs. Besides the writings above-mentioned, Mr. Ronalds is the author of an article in the *Philosophical Magazine* of 1814, entitled, "On Electro-galvanic Agency, employed as a moving power, with descriptions of a Galvanic Clock;" and other articles in the same journal, detailing his original experiments to illustrate the relations of *quantity* and *intensity* in the electric pile. He also wrote four Reports on the Kew Observatory, which were fully illustrated and printed in the reports of the British Association for the years 1845-50-51 and 52; and one paper in the Philosophical Transactions on "Photographic Self-registering Meteorological and Magnetical Instruments," written in 1846 and printed in the year following. In 1856 Mr. Ronalds published in French, at Paris, a summary of these reports, with some additions, entitled, "Descriptions de quelques Instruments Meteorologiques et Magnetiques," intended to explain his instruments at the French exhibition.

Mr. Ronalds is now (April, 1864) residing at Battle, in Sussex, and during the latter years of his life has spent much time, and part of his small pension, in collecting and collating an electric library, which might be conveniently available for the advancement of his favourite science, and prove worthy of presentation or bequest to some British public institution, so as to form the nucleus of one which might approximate possibly to a complete electrical library.

THE EGHAM ACCIDENT.

The daily press has very justly made some severe animadversions on the gross negligence and cupidity which characterise the management of the South-Western Railway. We quote the following from *The Times* and the *Herald*:—

"Colonel Yolland censured the whole arrangements made by the Company to meet the pressure of this extraordinary traffic. He gave it as 'his positive opinion that the system used in conducting it on the Cup Day was most dangerous.' He did not think sufficient protection was derivable from the signals, and he condemned the practice of running engines tender foremost. It is not pretended that on the day of the accident this practice operated prejudicially otherwise than by interrupting the communication between the guard and the driver, and even this interruption, as we have remarked, would probably have produced no mischief if the stoppages of the two trains had been known to both drivers. Still, the practice is undoubtedly a bad one, for it disturbs the adjustment of weight as originally designed, and it deprives the driver of the protection of the weather-board. There should certainly be turn-tables at Ascot as well as at Reading, because during the race week the Ascot station becomes virtually a terminus. For the rest, it is perfectly plain that every conceivable precaution is imperatively required when heavy trains running at great speed are started in such quick succession. The Company relied upon special instructions and multiplied signals, neglecting telegraphic communication between station and station, and dispensing even with the ordinary communication between guard and driver. These omissions, in the opinion of the jury, coupled with the lack of prudence in leaving the drivers uninformed, constituted 'general mismanagement' on the part of the Company, and left its erring servants 'under great disadvantages.' In other words, though the engine-driver and fireman of the second train were guilty of culpable neglect, there was considerable excuse to be made for them. That is the essence of most of these stories. If everybody did his duty under every imaginable circumstance without error or neglect, things might all go well; but with the first omission or fault they are liable to go wrong. The moral is that precautions should be so multiplied as to reduce to a *minimum* the risks which in default of perfect service must be sometimes expected."

"We are no advocates of vindictive verdicts; we believe that in many instances shareholders have been made to pay unfairly for the damage done by unavoidable disaster; we think that they frequently suffer for incompetence, neglect, and ignorance at the Board of Trade, but the want of a turn-table at a necessary point is not to be excused; the driving of locomotives tender first, which destroys the chance of precaution, is unpardonable; the absence of telegraphic communication can be justified under no circumstances whatever; while the confusion about stoppages, both at Egham and at Staines, exhibits an unwarrantable amount, so to speak, of practical levity, which language is hardly strong enough to condemn. We are anxious, while saying this, to do no wrong to the general direction of the South-Western Railway."

The following correspondence appeared in *The Times* on the 29th ult., in which it will be found that the valuable assistance the electric telegraph is capable of rendering to the traffic on railways is recognised by the secretary of the railway company on whose line the accident occurred, but its non-employment is excused on the ground that it would occasion delay, and give the public cause for complaint:—

To the Editor of the Times.

Sir,—Having read your excellent article relative to the accident on the London and South-Western Railway, I thought perhaps you might like to have the opinion of the secretary on the matter, and, as I do believe that it accords with that of the public, perhaps its insertion might induce those who value their safety more than the nominal advantage of arriving a few minutes before others on these great occasions to take the trouble to write to him to say as much; and perhaps the numerous remonstrances I anticipate that he would receive might have some effect in convincing him that the constant use of the telegraph would prevent the possibility of a verdict of manslaughter being returned against the directors for ordering their men to do that which will, sooner or later, be certain to produce more collisions.—I remain, sir, your obedient servant, Charles Mayhew.

June 28.

"6, Chester-terrace, Regent's-park.

"Sir,—As I have some little interest in the London and South-Western Railway, which by reference to your books you will find, I take the liberty of asking why you do not telegraph from station to station before starting the trains, and by so doing prevent the possibility of an accident. By not allowing one train to follow another until the preceding one has left the next station these fearful collisions could not take place, for which you not only pay enormously, but you do away with all confidence in your arrangements. On the Continent they adopt the plan I mention, and, if you have not, it is high time you did. I went down and back with one of my daughters on Tuesday by your train most comfortably, but I was afraid to take my other daughter to-day, because I could give her no assurance that another accident might not occur.—I remain sir, your obedient servant,

"Charles Mayhew.

"To the Secretary of the London and South-Western Railway Company."

"London and South-Western Railway, Secretary's-office, Waterloo-bridge Station, London, S., June 10, 1864.

"Sir,—I have to thank you for your note and its suggestions as to greater use of the telegraph than we at present adopt. The plan you have suggested is not of so easy a nature as you would suppose, and in practice would in so many instances tend to delay trains that I am certain the public would complain. Even now the slightest detention of trains is made a source of complaint, which would be immeasurably increased if the system of running only a single train at a time on the portion of railway between two stations were to be adopted.—I am, sir, your obedient servant,

"Frederick Clarke, Secretary.

"C. Mayhew, Esq., 6, Chester-terrace, Regent's-park."

Character.—There is a truthfulness in action as well as in words, which is essential to uprightness of character. A man must really be what he seems or proposes to be. When an American gentleman wrote to Granville Sharp that, from respect for his great virtues, he had named one of his sons after him, Sharp replied, "I must request you to teach him a favourite maxim of the family whose name you have given him: *Always endeavour to be really what you would wish to appear*. Once Cromwell said to Bernard—a clever but somewhat unscrupulous lawyer, "I understand that you have lately been vastly wary in your conduct; do not be too confident of this; subtlety may deceive you, integrity never will." Men whose acts are at direct variance with their words command no respect, and what they say has but little weight; even truths, when uttered by them, seem to come blasted from their lips.

THE PERSIAN GULF TELEGRAPH.

OUR readers are fully acquainted with the facts contained in the subjoined article; but as they have been arranged in consecutive order, by a gentleman deeply interested in telegraphy, we reprint them from our contemporary the *Engineer* as historical records.

We have much pleasure in announcing to our readers the safe submergence of the entire length of the Persian Gulf cable, and as the work is one of considerable importance, and has many points of novelty in the whole method adopted in carrying it out, we shall give a somewhat detailed account of the whole work with which we have been favoured.

It will be remembered that in the spring of last year the commencement of a submarine telegraph cable for the Persian Gulf was announced in several of the morning papers. The cable was to be submerged between Fau, near Bussorah, at the head of the Persian Gulf, and Gwader, on the Meckran coast, about 250 miles west of Kurrachee. At the same time a land line was being rapidly completed between Kurrachee and Gwader, while at the head of the Gulf a party of Royal Engineers were sent out to erect a land line between Fau and Bagdad.

Between Bagdad and Constantinople the land line has been completed for the last two years by the Turkish Government, but has never yet been of much practical use, partly on account of its stopping short at Bagdad, and partly through the line not being as yet brought into a thorough state of organization.

It was originally intended that the submarine line should be laid between Gwader and Fau, relying only on the Gwader and Kurrachee land line (commonly known as the Meckran telegraph) as the connecting link between Kurrachee and Gwader. It was, however, urged by Colonel Stewart, the director of the whole line, and chief adviser to the Government in this matter, that it would be more prudent to carry out sufficient cable to lay between Kurrachee and Gwader as well as between Gwader and Fau. Because, firstly, the Meckran line, running as it does through a wild, difficult, and rugged country, was liable to interruptions; and if these interruptions became frequent or of long duration, it would be difficult for our Government to bring pressure to bear on the Porte, with regard to the efficient maintenance of the land line between Fau and Constantinople, so long as this important portion of the British line was itself in an unsatisfactory condition. Secondly, because if any one of the ships carrying the cable were lost on its passage from England to the Persian Gulf, there would still remain sufficient cable to lay between Gwader and Fau; the Meckran land line being sufficient in such a case to form—for a time at least—the remaining link between Kurrachee and Gwader, until more cable could be brought out from England. The land line was constructed without much interference from the natives, under the able superintendence of H. K. Walton, Esq., now the general manager of the whole lines between Kurrachee and Fau; and with the exception of occasional interruptions, which have been quickly repaired, has remained in tolerable working order for the last year or so; indeed, were it not for the extremely curious and inefficient insulators which have been used and known as a patent of Sir W. O'S. Brooke, and which preclude the possibility of working the two wires as two separate circuits on account of the number of contacts which exist between the wires at the insulators on every section of the line, it may be considered as in effective working order.

To those acquainted with electric telegraphs the whole design of the posts and insulators will at once appear a mere monument of ignorance. The insulators consist of a cast-iron cap, made square on plan. For what purpose this form is assumed it is difficult to say, unless it is merely because all others have hitherto been made, without exception, circular. Inside this cap a cap of vulcanite is fixed by means of sulphur, and inside this again the supporting bolt is also fixed with sulphur. So far the insulator would pass muster, were it not that the sulphur has been carefully filled up to the very brim, so as to leave a flat surface between the bolt and the cast-iron cap, thus burying the whole of the vulcanite cap, and rendering it utterly useless, except to prevent direct contact between the bolt and cap, the whole insulating surface consisting of the flat surface of the sulphur between the bolt and the edge of the iron cap, this surface being unprotected from anything but mathematically perpendicular rain.

We thus have evidently a very bad insulator; but this is not all. It is well known that on lines of duplicate wires contact is more to be feared than a little want of insulation. To avoid the possibility of contact, therefore, on English lines, an earth wire is carried from earth up to the arm or arms, and twisted round them, so as to intercept any current between the wires, and carry it to earth. On the Meckran line, however, the arms, which are of iron and bolted together, are carefully insulated from the iron pole by three feet of wooden pole. The whole arrangement is, therefore, admirably adapted for preventing contact; the insulators are well adapted for allowing, on the smallest chance offered them of wet, a very fair conduction between the wires and themselves; and to avoid the possibility of this being interrupted by an iron pole leading to earth, the piece of wooden pole is carefully inserted between the arm and the iron pole, this insulating the iron arm from the earth.

In fact, it may be said that every care has been taken to give a chance of leakage, and further precautions are taken to ensure that the leakage thus obtained shall only be into the other wire. In fact, we cannot help remarking that, with the many excellently designed insulators which are now in use in Europe—and, indeed, on the railways in India, where the telegraph is not constructed by Government—it is a disgrace that, on a line where physical and political difficulties have been overcome, a double line of wires should only be available as a single line, through the system of insulation so strangely advocated by the late advisor to the Indian Government on telegraphic engineering. And it may be observed that the Government of India are themselves directly responsible for the wretched system of telegraphs under which the country has groaned for the last six or seven years, inasmuch as they, when telegraphs were well advanced in Europe, appointed a military doctor to do the work of civil engineers.

The wretched results are only too well known in India. The telegraph has simply become a matter of joke. As a single instance, we will only take the telegraph between Kurrachee and Bombay. A message between Bussorah and Bombay takes about five minutes to be transmitted from Bussorah to Kurrachee, through the cable just laid—a distance of about 1,300 miles; but here all certainty ends. The line between Kurrachee and Bombay—a distance, as the crow flies, of about 500 miles—is scarcely ever in working order; and when it is, the messages take on an average, without exaggeration, two days to go from Bombay to Kurrachee, or *vice versa*. Further comment is useless.

Reverting to our subject, the cable—1,250 nautical miles in length, weighing 3·75 tons to the mile—was constructed at Mr. Henley's works, North Woolwich, under the superintendence of Messrs. Bright & Clark, the engineers appointed to superintend the construction and submergence of the cable; the whole undertaking, including the selection and construction of the cable, the selection of engineers, and the construction of the various land lines, the arrangements of the stations and the permanent staff, being entrusted by the Indian Government to Lieutenant-Colonel P. Stewart, R.E.

With regard to the pattern of the cable selected we may first mention that the failure of long submarine cables in shoal water, such as the Red Sea and Mediterranean cables, has been proved on the best evidence to be principally due to the small quantity of iron used in the protecting sheath, and which again was allowed to perish rapidly through the absence of any precautions to ensure it against rust.

In the Red Sea and Mediterranean extension lines the protecting wires were scarcely so thick as bell wire, and not even galvanized; the whole cable weighing less than a ton to the mile.

These perished rapidly, as was expected by those who had experience in the maintenance of the cables around England, where the companies who possess cables have constantly laid them of larger and larger dimensions, the last laid weighing about 17 tons to the mile. The Malta and Alexandria cable weighs 2·13 tons to the mile, of which only 1·67 tons is iron, and the wire is ungalvanized and unprotected. It is curious that a cable of such a pattern, which cannot last for more than four or five years from the date of submergence without serious repairs, should have been decided on and laid, seeing that the Bonah and Cagliari cable, laid in almost the same locality and of precisely the same mechanical protection, was found broken up into short pieces by rust in about two years after submergence. This is the more to be regretted, as the core is of the most liberal proportions as regards copper and gutta-percha, and, indeed, the best insulated cable submerged up to the time of the Persian Gulf cable. In the case of the Persian Gulf cable, it is to be hoped that the precautions taken against this decay from rust will prove sufficient to ensure its effective working for many years to come. Of course the expense of transport from England to the Persian Gulf would make the adoption of a cable of the same weight and bulk as those used in the English and Irish Channels and North Sea excessively expensive, and add so considerably to the total cost of the work as to preclude, for the present at least, the adoption of a cable of such a weight; although undoubtedly the tendency will be to lay cables of a heavier description on each successive work, if in shoal water, even though undertaken abroad. It is to be remarked also that, with the exception of a few rough patches between Gwader and Kurrachee, the whole of the line lays in quite soft mud, into which all leads, anchors, and grapples sink several feet deep. The amount of anchorage, except from small native craft, is also insignificant, and therefore a very heavily proportioned cable would be unnecessary.

Still the proportions and weight of the Persian Gulf cable is 3·75 tons to the mile, of which 2·95 tons is iron. In addition to this advantage in the quantity of iron, the iron wire is all galvanized, a process which, it is well known, generally adds some years to the life of a cable. In corroboration of this it may be mentioned that, in the operations connected with the repairing and picking up of the Red Sea line in 1862, under the superintendence of Mr. L. Clark and Mr. Laws, the ungalvanized cable was found entirely perished, while a few feet off the galvanized wire was found in perfect condition. To secure the cable still more against the danger of rust, a process invented and patented by Messrs. Bright & Clark has been adopted, which, although already in use on several cables about England, has never yet been so perfectly carried out as in the present case.

Before proceeding to describe this we must give a brief description of the whole pattern of the cable. The conductor, unlike cables hitherto laid, consists neither of a single copper wire, as at first adopted in all the earlier cables, nor of a strand of three, five, or seven wires, laid up so as to form a small copper strand, as in the case of the Atlantic cable and Malta and

Alexandria. The former mode presents the disadvantages that, when the wire was brittle from unsound casting in the ingot or bad annealing, it was liable to crack, and when being paid out from the ship the two parts separating would cause a want of continuity, thus rendering the cable useless until the faulty part was cut out.

The second method obviated this danger, as it is improbable that several wires should all have brittle places exactly at the same place in the rope; but other disadvantages presented themselves, as science advanced, of a more delicate nature.

It was proved mathematically, and found in practice, that the increased amount of surface exposed in proportion to the sectional area of the copper in the case of the strand conductor, as compared to the solid wire, reduced the rate of signalling greatly. Besides which, it was found that the interstices in the strand wire permitted the water to percolate along the cable whenever an end was left open in any of the operations exposed in the sea.

To combine the advantages of both systems without their respective disadvantages, Mr. L. Clark suggested a conductor formed of four wires, whose section is each the quadrant of a circle; so that when the four are placed together they form a complete circle, and are kept in their places by a fifth part in the form of a tube encircling the four segmental wires. We thus have a circular conductor formed of five separate parts.

This system, which lessens the chance of loss of continuity, preserves all the electrical advantages of the solid circular conductor, and has been adopted for the first time on the cable we are describing. To ensure also the highest conducting power, each hank of copper was carefully tested for its conductivity, the bad being rejected and an extra price given for all copper which was above a certain fixed standard of conductivity, this standard being equal to the copper of highest conducting power hitherto used. To assist the manufacturers in the selection of their copper, Mr. Brasher, an assistant of Messrs. Bright & Clark, made a series of experiments on the conductivity of the ingots previous to their being drawn into wire at the works of Messrs. Wilkes, by whom every facility was given for these operations. The diameter of the conductor is 0·1 of an inch, and weighs 225 lbs. per nautical mile.

We now come to the insulating material. A great deal of discussion has taken place of late amongst electricians and manufacturers, relative to the respective merits of india-rubber and gutta-percha. Fierce has been the battle that has been waged at public institutions and in scientific journals by the untiring partisans of each insulating gum. Papers have been read, experiments have been made, champagne breakfasts and special trains have been provided for special meetings, with the hope of proving to engineers, electricians, and directors the superiority of one or other gum. Discussions in the press have more than once verged on the personal, through the conflicting opinions and interests of the different advocates of each particular gum. India-rubber has set forth its advantages in glowing terms, and proved over and over again that all cables insulated with percha must fail, while percha has taunted india-rubber with its utter unfitness for the purpose, until the battle of the gums has become as notorious as the "battle of the gauges." It would seem at first sight, therefore, to be a difficult matter (amongst so many conflicting opinions and interests) to decide on the best insulator for so large and important a work as the Persian Gulf cable, particularly if we take into account the number of failures which have taken place in submarine telegraphs, and which are, one and all, laid by the advocates of india-rubber in the most unscrupulous manner to the adoption of gutta-percha as the insulator.

To those who examine more carefully the evidence which has been published on this subject, it will be easily seen that those failures can be traced more to want of sufficient mechanical protection in most cases, and in others to carelessness in manufacture, or a want of skill in the operation of submergence, than to any deficiency in the insulator used. Gutta-percha has been used on many cables ever since the year 1851 with perfect success, and evidence is still wanting to show that it deteriorates when kept under water, although many cables have been lifted and carefully examined in various seas; while india-rubber, whatever part it may ultimately play in submarine telegraphy, has never yet been employed on any submarine line; and, indeed, in the only practical experiment which has been made to ascertain its durability—viz., the submergence of a length of two miles off Kurrachee—proved a complete failure.

The facts were, therefore, not such as would justify any departure from the course hitherto adopted, more especially as the Gutta-percha Company have made great progress during the last few years in cleaning and manufacturing the gutta-percha used for submarine cables, and could, it was well known, produce a far better insulator than had hitherto been employed.

Colonel Stewart, with whom rested the final decision of this matter, although well acquainted with the facts we have mentioned, prudently requested the opinions of the chief scientific authorities, among whom we may mention Messrs. Bright & Clark, Professors Thomson & Wheatstone, Messrs. Varley, Jenkins, & Siemens, the majority of whom decided in favour of gutta-percha. But although at the present time there can be little doubt as to the superiority of gutta-percha over any other substance for this purpose, still the improvements that have been made during the last three years in the preparation of india-rubber, through the untiring perseverance and skill of Messrs. Hooper, Silver, and Hall & Wells, give great hopes that the well-founded objections to the use of rubber may be, ere long, removed. India-rubber, when first manufactured, has, it is well known, superior insulating qualities, as well as a lower specific inductive capacity, and in addition will stand a greater change of temperature without affecting materially its insulating power—a quality which is of the highest importance in tropical climates.

Its chief disadvantages at present appear in a tendency to change its solid for a semi-fluid state, resembling that of treacle; in other cases it becomes hydrated after submersion. How far vulcanization will remedy this evil still remains to be proved.

But in addition to these various drawbacks, the mode of applying the material, which consists in lapping it spirally round the wire, thus forming a spiral joint the whole length of the cable, cannot (however perfect it may appear when first made) be so safe as the mode adopted in covering with the more plastic material, gutta-percha, which consists in passing it through a die for each successive coating, in which case the covering consists of a series of concentric tubes, forming a continuous and unbroken coating. The whole of these layers are cemented together during the process by a layer of insulating material known as "Chatterton's compound." How far the late attempts to remedy the objections to india-rubber will prove effective will be proved by the results obtained on the various lengths of experimental wire which Colonel Stewart has, with a laudable desire to investigate thoroughly the whole matter, taken from England for the purpose of submergence in the Persian Gulf.

The core of the Persian Gulf cable, then, consists of the conductor, which we have described, insulated with four coatings of the purest gutta-percha, united by four distinct layers of "Chatterton's compound," having an ultimate diameter 0·38 of an inch, and weighing 500 lbs. to the nautical mile (225 lbs. of copper, 275 lbs. of percha).

The core was also manufactured in much longer sections (sometimes nearly 4,000 yards in one unbroken length) than any that had been hitherto made, thus reducing the number of joints in the whole cable considerably—a great advantage, as the joints are found electrically to be the weakest points in any core. The core thus manufactured was presented to Government for testing at the Gutta-percha Works.

These tests were made by Mr. J. C. Laws, assisted by Mr. Lambert on the part of Messrs. Bright & Clark, and consisted—firstly, in a careful test by means of Wheatstone's electric balance, to ascertain the resistance of the copper per nautical mile, expressed in terms of Siemens' well-known unit of resistance; secondly, a test of the resistance of the gutta-percha, or, in fact, its insulating quality, expressed also in terms of the same unit as the copper resistance. Both these materials are affected in their conducting power by temperature to a great extent. The effect of an increase of temperature on the gutta-percha is to lessen its resistance; whereas with copper, on the contrary, the effect of an increase of temperature is to increase its resistance.

Very different results would be obtained, therefore, with the same materials at different temperatures, and thus testing at the ordinary temperature in England would be very different to that which would be obtained in the Persian Gulf.

To avoid these sources of error the wire was tested at one uniform temperature, which was obtained by immersing the coils in water kept at 24° centigrade for at least twenty-four hours previous to the test being made. The wire was also tested at the same temperature in Reid's pressure cylinders under a pressure of 600 lbs. to the square inch, which is equal to a depth of 200 fathoms, a depth far greater than that at which the cable will be submerged.

(To be continued.)

SILVER'S INDIA-RUBBER WORKS AND TELEGRAPH CABLE COMPANY (LIMITED).

An extraordinary general meeting of the shareholders of the above company was held on Thursday last at the London Tavern, Bishopsgate-street, for the purpose of obtaining the sanction of a special resolution of the company to the making of new regulations and provisions for—

First. The increase of the capital of the company by the issue of new shares; such aggregate increase to be of such amount not exceeding £500,000, and to be divided into shares of £50 each, or of such respective amounts, and to be allotted in such manner as the company in meeting shall direct, or, if no direction be given, as the directors shall think expedient.

Second. The change of the name of the company from "Silver's India-rubber Works and Telegraph Cable Company (Limited)," to "The India rubber and Gutta-percha and Telegraph Works Company (Limited)," according to the power given by the 13th section of "The Companies' Act, 1862."

Third. The substitution of the following regulation in lieu of the regulation now contained in Article 44 of the Articles of Association of the company:—"All capital and all other moneys of the company not immediately applicable for any payment to be made by the company may be deposited or invested by the directors in or upon such personal or other securities or investments, other than stock or shares of the company, as the directors from time to time think proper."

Dr. Beattie occupied the chair.

The SECRETARY having read the advertisement convening the meeting,

The CHAIRMAN remarked that he had great pleasure in meeting them so soon after the formation of their company, which had for its object the extension of the works of Messrs. Silver & Co., in the manufacture of articles of india-rubber, to which was to be added that of gutta-percha, as well as the new gum, balata, which was likely to become an article of great commercial importance. It having come to the knowledge of the board that another company, with powerful support, was about to be formed to work gutta-percha, they felt that if it had been started it would have produced serious competition with this company; they therefore deemed it desirable that arrangements should be attempted to produce a fusion of the two interests, and they are glad to report that such a fusion had been accomplished, and thereby competition had been prevented, whilst very considerable collateral advantages would be obtained. When he mentioned that by this amalgamation Messrs. Harvey and Henderson had been added to the board of directors, they would at once perceive that the board had been very much strengthened thereby. Messrs. Silver having learned that the proprietors of the india-rubber and gutta-percha factories of France and Belgium were in some difficulties, it was thought advisable to ascertain on what terms these works could be purchased, and after some great degree of trouble, and the visit of some of the directors to Paris, it was agreed to purchase the works in Paris and Belgium, and an amount of £65,000 has been paid for the freeholds and the works, and a concession has been made by which the proprietors may acquire £100,000 in shares in the company's works. It was also most important to state that no promotion fee was to be paid to Messrs. Harvey and Henderson. The next question he had to refer to was the nominal capital. It was evident that the extended works could not be efficiently carried out with their present capital; it was therefore proposed to increase it from £500,000 to £1,000,000, and to allot £250,000 of new issue, of which the French company was to have the option of taking £100,000, and the new gutta-percha company £150,000, of which they had pledged themselves to take £100,000, leaving the other £50,000 for disposal amongst their friends. It would, therefore, be very obvious that their company would acquire great strength by that arrangement. They had not brought the new gum, balata, much before the public at present, but they expected very much from its introduction; and he might remark, that at the late distribution of prizes at the Society of Arts, by his Royal Highness the Prince of Wales, the silver medals of the Society were presented to Sir William Holmes, and Mr. Walker, of Demerara, for introducing it to public notice—a fact which spoke favourably for the gum itself. The next thing he had to bring before them was the change of the name of the company from that of "Silver's India Rubber Works and Telegraph Company, Limited," to "The India Rubber and Gutta Percha and Telegraph Works Company, Limited," which had been necessitated by the amalgamation of the new company with theirs. Within the last three months the business of the company had increased twenty per cent. over that of the same three months last year, whilst in one department, since May, 1863, the operations had been trebled. The unfortunate fire, some time since, at Silvertown, had caused some anxiety to the shareholders, but he was enabled to inform them that the damage had caused very little interruption to the works. The whole has been covered by the amount of insurance and salvage, with the exception of a small sum, which Messrs. Silver had, in the most handsome manner, taken upon themselves, which he thought it right the shareholders should be made acquainted with. The next part of the business of the meeting, relating to the investment of the capital at the disposal of the directors, had been rendered necessary by the regulations of the Stock Exchange.

The CHAIRMAN having read the whole of the resolutions, concluded by proposing the first, relative to the increase of the capital.

J. W. WILLANS, Esq., explained, in answer to a Shareholder, that only £250,000 worth of shares had been issued in the first instance, and that, supposing that the French Company took up the whole £100,000 which had been apportioned for them (of which the Board were not certain), and Messrs. Harvey and Henderson the £150,000 set apart for them, there would still be opportunity for further investment in the remaining shares of the company.

J. G. T. CHILD, Esq., in seconding the resolution, said that on account of the new arrangements made it was found necessary to have a much larger capital than was originally intended; they were bound, however, to keep faith with their shareholders, by not issuing new shares, and by not making calls more rapidly than they had engaged to do. It was therefore suggested that, as they could not issue these shares, they must create new ones; and they had determined upon the creation of £250,000 in new shares, and thus leave the original in *statu quo*. He thought that the proposition would be found desirable, so that they might be able to make calls as they required money, which, he thought, would be found better for all parties.

The resolution having been put to the meeting, was carried unanimously.

The second resolution, relating to the change of name of the company, having been moved by the Chairman, and seconded by Mr. M'Clure, of Manchester, was also carried unanimously.

The CHAIRMAN having moved the next resolution, relating to the cash in the hands of the Directors, stated that on account of the progress of telegraphy in the East, they contemplated that a very large and profitable business was likely to be done almost immediately in that department.

Mr. ATKINSON did not consider it desirable to have so large an amount of money at the disposal of the Directors, to invest in any way they pleased. He thought they ought to deposit it at the bankers.

The resolution having been seconded, was put to the meeting, and carried unanimously.

Mr. JONES, of Huddersfield, felt that it was most satisfactory to have such an explanation as they had heard with regard to the fire at Silvertown, and it was doubly so to find that the loss had been covered by Messrs. Silver. He therefore begged to move, "That the hearty thanks of the meeting be given to Messrs. Silver, for the very handsome manner in which they had secured the Company from any loss which might have arisen from the late fire at Silvertown."

Mr. F. CASE having seconded the resolution, it was carried unanimously.

Mr. S. W. SILVER begged to thank them for the kind way in which they had taken notice of the manner in which the loss by the late fire had been met. They had great cause for thankfulness that matters were not worse than they had been. He looked with a deep sense of gratitude to Him who rules the winds, that He was pleased not to permit the whole of the place to be levelled with the ground. He could only say that they were very glad to meet the calamity in the way they had done. (Cheers.)

Mr. CHILD moved and Mr. JONES seconded a vote of thanks to the Chairman for presiding, and also for the great attention which he paid to the interests of the company, which was carried unanimously.

The CHAIRMAN, in acknowledging the vote, said, that he looked forward with confidence to a large amount of business being done by the company, not on this side of the Atlantic only, but on the other also. He then announced that the meeting would stand adjourned to that day fortnight, for the confirmation of the resolutions of the present meeting.

THE AMERICAN COMMISSIONER ON THE POLICY OF PATENTS.

(*Continued from page 306.*)

The system of granting patents in Great Britain without previous examination as to novelty has led to the granting of a great number of patents for the same thing—an evil which became so great as to lead to the publication of all the specifications, which only partially remedies the evil. Mr. Woodcroft says, "that having found so great an abuse to exist, as to granting patents for the same thing over and over again, he was led to prepare a list of those which related to the origin and progress of steam navigation." "I found," he says, "that no step in the art of steam navigation had been made which was not the subject of a patent. Among 400 patents, I found that a very few heads would comprise the whole of the inventions; for instance, of vertical paddle-wheels there have been a score of patents which are identically the same in mechanical action; for drawing water at the bow of a vessel and pumping it out at the stern there have been another score or two; then for making the float-boards of paddle-wheels move in various directions on their axes, there have been also as many patents; and for propellers in imitation of ducks' feet there has been a large number of patents." A striking instance of the evil resulting from this system is taken from Mr. Woodcroft's evidence. He says: "I have known of a patent within the last year upon which a gentleman had spent about £11,000. He came and consulted me, and wanted me to go and look at a boat he had been constructing. I said, 'It is of no use. I have seen the drawing, and the invention is as old as the hills, and you will never drive the boat six miles an hour; in addition to that, the invention is not yours—it has been patented over and over again.'" Mr. Hodge, an English patent agent, who had personally witnessed the practical working of our system of examination and heartily approved of it, speaking of the English practice, says: "Many inventors have been ruined in consequence of taking out patents under our (the English) system; whatever amount the patent may have cost the inventor, it may be assailed the very next hour. I can refer to a case in which a patent was tried before a special jury; upon their decision being given, the patentee went out of court saying he was a ruined man. And if he had not had a few friends to come and support him he would have been ruined. If the Government had appointed a board of examiners to examine his patent, and to show him that it was not quite original, and that there was a little infringement upon another patent, he would not have had occasion to go to this great cost."

The evils of this system were many years since pointed out in an able article on patents published in the *Edinburgh Encyclopedia*, and written by Mr. Simpson, under the direction and sanction of the eminent philosopher, Sir David Brewster, himself a patentee, whose beautiful optical toy, the kaleidoscope, some years ago, used to delight so many thousands of children, and even wise men, with its wonderful changing polychromatic beauties. This writer, after a severe reprobation of the then existing system of patents, observes, "The causes of these aggravated mischiefs are both before our readers, when we say that patents ought not to be granted *of course*, and 'at the hazard' of the patentee, but *causa cognita*, by a sufficient and competent authority." He continues: "The expression is common, that a patent may be got for anything, but very few are found good when they come to the ordeal of a jury. Is not this saying, in so many words, that many that have ought not have been granted, and that it is unworthy of this great country to pervert a valuable privilege, and confound the trash of every

pretender, whose end is answered by a mere patent mark, with those inventions which illustrate the genius and exalt the character of the people?"

More than thirty years afterwards Sir David Brewster declared that his opinions were clearly expressed in the article above quoted, that the protection of patents ought only to be extended to *new* ideas, and that he would ascertain the novelty of such ideas by means of a board of commissioners composed of scientific persons. It is due to the pervading knowledge that a patent in Great Britain is not even *prima facie* evidence of the originality of an invention, and that it is of little value, except to give the patentee a status in the courts until it has passed a judicial ordeal, that such severe litigation exists in that country in relation to titles to inventions. The costs of such litigation are sometimes frightful. Two startling instances are related by Sir Hugh Cairns in the speech in the House of Commons before referred to. A patent had been taken out by an eminent manufacturer in Sheffield for an invention which effected a revolution in the manufacture of steel by the introduction of a chemical substance, and enabling steel to be produced at a reduction of 30 or 40 per cent. on the previous cost. Mr. Heath, the alleged inventor, from the time he obtained the patent, in 1842, till he died, in 1853, spent his life in litigation. The suit was formally carried to the House of Lords, and he obtained a statement which showed that the costs of the defendant were estimated at £7,000, and those of Mr. Heath at £8,000, showing that the two sides had expended in litigation connected with a single patent the sum of £15,000. It appears by the statement of a writer in the London *Quarterly Review* that this patent was extended in 1853 for the benefit of Mrs. Heath. In August, 1853, Mrs. Heath brought an action against an infringer, and *then, for the first time*, credible evidence was given that the invention was not new at the date of the original patent. A patent was taken out in 1850 or 1852 by a Scotch gentleman named Menzies for capsules and tops of bottles. The invention being a very valuable one, litigation in connection with it was carried on both in Chancery and in the courts of common law. After, according to Mr. Montagu Smith, a verdict in favour of the patentee, the case was taken to the Queen's Bench, where the patent was defeated on the ground that an *old patent had been discovered* in the office by which the invention had been anticipated. Finally, the case was carried by appeal to the House of Lords, where, in 1862, it was still pending. Sir Hugh Cairns stated that the solicitor to the plaintiff informed him that the costs of his client amounted to £14,487, and he estimated those of the defendant at £10,370. So that the total costs of legal proceedings in connection with the invention amounted to not less than £24,857. The legal expenses connected with these two patents, which might have been saved to the unhappy litigants by a system of preliminary examination, was £39,857, or about $199,285, about $10.000 more than the total expenses of this office for the last year—viz, $189,414 14c., which, during this period, has made examination of 6,014 applications. Of these applications, 1,844 were refused, principally upon the ground of a want of novelty, while 4,170 patents have been granted. It is not pretended that errors from unsoundness of judgment or insufficiency of investigation may not have occurred in these decisions. But I feel confident that, as the general result of our system, its benefits have accrued no less to the unsuccessful than to the successful applicants; that while the latter have secured patents to which an intrinsic value has been imparted by the scrutiny to which the inventions have been subjected, and by the sanction of the office are comparatively protected from infringement and litigation, the former have been saved from waste of time and labour upon well-known machines, and from the cost and misery of defending in courts of law rights to which they could maintain no title. This view of the benefit of a system of examination in preventing infringement and litigation is fully borne out by observation in Prussia, where there is an admirable plan of examination as to novelty by a board of patent commissioners, each one of whom is selected for his proficiency in some special department of the arts. Mr. Weddinge, a member of the Board of Trade of Prussia, as well as a member of the patent commission, stated, before the committee of the House of Lords, that in Prussia there are very few infringements of the patent rights of patentees, and that manufacturers generally prefer to get permission of the inventor to use his right under the patent. It is true that litigation to no inconsiderable extent will always exist in this country, where such vast capital is invested in patent property, and especially in relation to questions of interference, or those where the question of priority arises between two inventors, both of whom may have been original authors of the discovery; but the amount of present litigation is trifling compared with the vast number of patents issued, and the value of property based upon them. I assume merely that litigation is most materially prevented by our system of examination. If even this is true, it is the highest commendation of our system, for, as Lord Langdale, the late Master of Rolls in England, says, "It is the great object of good legislation to cut off the causes or sources of litigation; that I conceive to be the object of Government." It is the duty of patent agents, who now form so important a class of professional men in this country, not too earnestly to press doubtful applications, and not to demand of the office a liberality in granting patents, which, if carried too far, would destroy the system which is the foundation of their business. It is the duty of the office to conscientiously and rigorously scrutinize every application, and to be sure that no patent is granted for anything which is not absolutely new, and at the same time to see that the applicant shall have the benefit of whatever, whether claimed or not, which is shown by specification, model or drawing, to be a new invention. That both these objects have been kept in view by the office—at least under its more recent administration—is shown by the fact that more than half of the applications upon which patents are granted are amended by the applicant at the suggestion of the office, so that he may not claim any more than has been found by the office examination to be actually new. The reasons urged by Lord Stanley and Sir Hugh Cairns, in the important debate so often referred to, that a patent should be granted after an inquiry little more than nominal and formal, it being understood that it should confer nothing more than a right to sue in a court of law, were, that it would be difficult to find men who were competent to pronounce authoritatively upon the novelty and utility of an invention, and that if scientific men were selected to compose a tribunal to pass judgment upon the novelty and utility of an invention, those inventions which were most original, and which in the end would be likely to turn out most valuable, would be most unlikely to receive scientific sanction. It was urged, for example, "Sir Humphrey Davy did not believe in the possibility of lighting houses with gas, and had he been acting as a judge, would have condemned that invention as useless." The last objection applies only to the examination as to utility, upon which with us the office does not pronounce judgment. The readiness with which persons acquainted with any particular branch of invention, and provided with facilities for investigation, can determine questions of novelty, is admitted by Mr. Woodcroft, although opposed to the system of examination. Being asked by the select committee whether, supposing he were professionally employed to determine for parties upon the novelty of their inventions, he thought he could undertake generally to determine that point with a moderate degree of time and expense, he replies, "If I had the whole of the specifications before me, I could do it in a moderate degree of time, and at a moderate expense." The facilities for determining the novelty of inventions demanded by Mr. Woodcroft are most amply provided in this office. It possesses a technological library unequalled by any in this country.* It has opened relations with nearly all the Governments in the world for obtaining information up to each current month of the progress of inventions abroad. Its portfolios of drawings, so numerous as to crowd two halls, each nearly 100 feet in length, and yet so systematically arranged that the hand can at once be laid upon any drawing sought for, and its museum of models, unrivalled by any similar collection in the world, exhibit as in an open book all that has been done in American inventions. It is the fault of the administration, and not of the system, if the plan and facilities for examination are not as perfect as human ingenuity has devised.

Another favourable point of comparison of our own with the English policy is the cheapness with which patents are obtained in this country, the cost being limited to the amount necessary to create a fund for reimbursing the expenses of the Patent-office, while in Great Britain the cost of obtaining a patent is £175—over twenty-two times the cost in this country. From the fund accumulated by these fees in five years there was deducted for stamp duties the enormous tax of £67,060. It was in relation to this great grievance that Lord Stanley said, in a pamphlet published in 1856, "One discovery checked, or even retarded by exhorbitant imposts, may cause a greater diminution of wealth, which would otherwise accrue to the nation,

* About 14,000 volumes have already been collected. Few or no libraries in the country are so complete in many of the departments of useful knowledge. The collection of encyclopedias, and of scientific and technological journals, cannot be surpassed. Of journals it possesses not only the leading ones of this country and Great Britain, but those of France and Germany, and also those in the separate departments of science and arts. For example, in photography there are 3 American, 4 English, 5 French, and 3 German. The office subscribes to 95 periodicals, and receives 75 by donation, in addition to the transactions of learned societies. Of these periodicals 69 are in the English language, 27 published in America, and 42 in Great Britain; 35 in the French language, 57 in the German, 2 in the Italian, and 2 in the Dutch. Of these, 11 relate to general science, 26 to arts and manufactures, 15 to photography, 7 to civil engineering, 7 to horticulture, 4 to mining, 6 to chemistry, 2 to chemistry and physics, 2 to chemistry and pharmacy, 34 to agriculture, 11 to literature, 3 to bibliography, 3 to statistics, 3 to mercantile affairs, 2 each to acclimatization, manufacture of paper, railroad engineering, entomology, gas lighting, patents, military affairs, and architecture; and 1 each to fine arts, microscopy, law, electricity, medicine, medicine and surgery, pharmacy, veterinary surgery, horology, coal oil, coach-making, printing, bees, botany, and geology.

During the past eight years the office has sent its reports to all the principal libraries and learned societies in the world, and received in return many valuable works, besides the regular publications of the societies. From the Great Seal Patent-office of England, for example, it has received a complete set of its publications, forming a library in themselves, consisting of the specifications of patents of the old law series, issued prior to October, 1852, to be bound in 408 volumes of 8vo letter-press, and some 350 volumes of folio plates, 378 volumes of letter-press, and 378 volumes of plates of the new law series, 35 volumes of indexes, 10 volumes of the *Commissioners' Journal*, 25 volumes of abridgments of specifications, 1 volume of appendix, and 1 volume of supplement.

To enumerate the more valuable works in this library would be a long and tedious task, as it is well supplied in all its various branches, embracing in the simple subject of photography, the literature of which is of recent growth, 144 separate and independent works, not including its periodicals. During the year 1863, 574 volumes and 114 pamphlets have been added to the library. Of these, 808 were by purchase, and 380 by donation.

As the business of the office extends and the number of patents is increased, the library will become a more and more important auxiliary. Its use is not confined to the examining corps, but is extended to the inventors of the country, and to solicitors and attorneys from the distant cities. To those engaged in the trial of patent cases before the courts it is invaluable, as it is impossible to find so complete a history of the improvement in litigation as upon its shelves.

A liberal spirit ought always to be exercised in the purchase of books, and every means taken to render the library complete, that it may at all times show the condition of the arts. Unfortunately, during the past three years, owing to the decrease of the receipts, it has been necessary to limit the expenditures, but with returning peace large additions ought to be made and improved accommodations be secured. The example of the Great Seal Patent-office, which within a few years has accumulated a library of upwards of 40,000 volumes, may well be followed.

than can be compensated by tenfold the gain actually netted by the treasury." The acknowledged object of subjecting patentees to these enormous charges is the prevention of the multiplication of worthless or frivolous patents, and patents for small improvements on valuable inventions, or combinations thereon.

The objections to the frivolity and multiplicity of patents are so often thoughtlessly made, even in this country, as to be worthy of refutation. Those who have carefully studied the progress of civilization must have observed that the uplifting of society has not been effected by paroxysmal convulsions, such as were supposed by geologists of former times to have upheaved the ancient continents at a single shock, but by causes which have operated as gradually and imperceptibly as those which modern science has shown to have actually raised within historic periods vast countries, with the whole burden of their cities and unconscious people. The progress in mechanical improvements and in science has been so gradual, that it is difficult to trace it except by the great general results. The fields of invention and practical knowledge have been extended by accretions as insensible as those which have formed the delta of the Mississippi. Every new fact in science—every new conception of ingenuity—no matter how trivial, has added something to their area. The noblest inventions which now astonish the world—the steam-engine, the cotton mill, the railroad—have been as truly built up block by block, layer by layer, as the pyramids. More than eight hundred distinct inventions were required to perfect the cotton-spinner. To refer to more recent branches of mechanical industry, we find some of the best harvesting machines protected by no less than twenty patents, each invention consisting of but a trivial improvement, yet the whole being necessary to the perfection of the machine. The art of sewing by machinery, which originated no later than 1842, has attained its almost miraculous development in this country through more than six hundred inventions, for which patents have been issued. It is by no means asserted that all these inventions have been found practically useful; but perhaps no other art can so well illustrate how, in mechanical contrivances, idea begets idea, and the invention of yesterday gives birth to the invention of to-morrow.

The apparent insignificance of an invention is no measure of its value. Inventions in the meanest of household arts, such as improvements in washing and wringing machines, have not only contributed most materially to domestic comfort, but have given rise to single manufacturing establishments employing over half a million of dollars of capital. Improvements in articles so trivial as hooks and eyes, and pins for infants' clothing, have been the foundation of patents which have produced tens of thousands of dollars.

The application, in a manner to be hereafter described, of a *pencil mark* in submarine blasting, and the explosion of military mines by the electric current, enables the operator to dispense with cumbersome and costly batteries and machinery formerly indispensable. A spring for holding the deflector and chimney upon a coal-oil lamp, consisting simply of a bent strip of brass, has gone into universal use, and through a tariff of a few mills upon each lamp to which the invention is applied, has yielded several hundred thousand dollars to the inventor. The more minutely the arts are studied, the more will the conviction be forced upon the mind that, as the distinction between great and small appears to be unrecognized by Providence, the distinction between important and trivial, and useful and worthless, should never be applied to any original work of human ingenuity.

This is the doctrine of Sir David Brewster, who believed that "patents should be granted for every new idea, whatever that idea might be; that every encouragement should be given to persons to bring forward such ideas; and that, instead of throwing difficulties in their way, even when the ideas appear to be frivolous, every facility should be given for their development, because they may contain the germ of future inventions. They may contain ideas which will suggest others more useful and practical; and what is a simple and amusing experiment in one age may become a great invention in another."

(To be continued.)

CORRESPONDENCE.

JOINTS IN TELEGRAPHIC CORES.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—I am glad that you have called attention to the above important subject. There can be no doubt but that several thousand miles of submarine lines have failed owing to the slovenly and imperfect manner in which the joints were made. The greatest care should be exercised in the making of joints in both gutta-percha and masticated india-rubber covered wires. Good, efficient, and permanent joints are practicable in either material; not so, as you observe, with virgin rubber, vulcanised rubber, Wray's compound, and many other materials. Neither an efficient or permanent joint has ever yet been effected. I believe that the unsatisfactory condition of the line between Kurrachee and Bombay, as described in your last number, is owing to the imperfect insulation of a short cable, consisting of a combination of virgin and masticated rubber, lately submerged as a part of that line, the condition of which cable joints were the subject of conversation amongst electricians previously to its leaving our shores. To show the importance attached to the proper rendering of a joint, the following extract from the evidence of Mr. W. Smith, before the Submarine Telegraph Committee, will suffice:—" Capt. GALTON: Is not the making of the joints the most difficult part of the manufacture?—Mr. W. SMITH: It requires great care. Capt. GALTON: Do you employ peculiarly skilled men for that purpose?—Mr. W. SMITH: We have men who do nothing else."—Yours truly,

June 28, 1864. A. J. T.

TELEGRAPHIC NEWS.

BALATA.—At the annual meeting of the Society of Arts, held at Willis's Rooms on the 27th ult., his Royal Highness the Prince of Wales, on behalf of the council, presented the silver medal of the society to Sir William Holmes for the introduction into this country of the above valuable material as a substitute for gutta-percha and india-rubber for insulating and other purposes.

MERIT REWARDED.—We are glad to find from an intimation contained in the *Moniteur Universel* of the 24th inst., that his Imperial Majesty the Emperor of the French has conferred upon Professor Hughes, the inventor of the well-known instrument which bears his name, the honour of a chevalier of the imperial order of the Legion of Honour. We heartily congratulate the distinguished electrician on this additional recognition of the valuable services rendered by him to the science of telegraphy.

THE PERSIAN GULF TELEGRAPH.—We are glad to be able to announce the safe arrival in England of Sir Charles Bright, and to report that his labours in laying the line which is to connect Europe with India have been eminently successful. The gentlemen of the staff have not yet arrived, but are expected in a few weeks. Mr. F. C. Webb remains in India to superintend the preliminary working of the line.

WEST INDIA ISLAND TELEGRAPH.—It is stated that a proposition has been lately made to connect most, if not the whole, West India islands by telegraph with the Mainlain at Cayenne, in French Guiana, at Key West, in Florida, if a grant of £6 per cent. on the outlay can be obtained. The cost is estimated at £300,000. It is proposed that Cuba should subscribe £2,500 per annum, Trinidad, Surinam, Porto Rico, Demarara, Barbadoes, and Jamaica, £1,500 each, Martinique and Guadaloupe £1,000 a year each, and St. Thomas, Cayenne, and Santa Cruz £500 a year each.

FRANKING TELEGRAPH MESSAGES WITH STAMPS.—The application of stamps similar to those used for letters is now being tried at Berlin for telegraphic dispatches. The administration has for this purpose had stamps struck off at 8, 10, 12, and 15 silbergros. The person sending the dispatch sticks on the manuscript copy the number required to represent the sum stated in the tariff. In case of insufficiency, the clerk calls on the sender to pay the difference. The experiment is only at present being tried in one of the telegraphic offices of the Prussian capital, but if it succeeds the plan will be generally adopted throughout the kingdom.

ANGLO-INDIAN TELEGRAPH.—We have received intelligence from the disturbed district between Bagdad and Bussorah to the effect that the rebel Sheikh Mansuha had collected together some five or six thousand of the Montefic insurgents, and had attacked Fahad (the Sheikh nominated by the Turkish Government), whose force was supported by twelve hundred Turkish infantry and two guns. Mansuha was routed with great loss, and fled over to the other side of the Tigris. The country is now assuming a more settled state, and mounted messengers are being sent over the break between Diwanyeh and Bussorah every two days, occupying three and a half to four days in the journey. The line between Bussorah and Kurrachee works with the greatest possible celerity and efficiency, but it will be necessary to bring about a reorganization of the Constantinople and Bagdad land line, especially in stationing European signallers at the chief stations, before it can be properly worked for through traffic. Colonel Stewart is now on his way from Bombay to Constantinople to complete these and other essential arrangements.

THE RUSSO-AMERICAN TELEGRAPH.—The proposed Inter-Continental Telegraph, which, viâ Behring Straits, will complete the circuit of the world was recently the subject of discussion in the New York Chamber of Commerce. It appears that Russia has undertaken a line of 6,000 miles from Moscow to the Pacific Ocean at the mouth of the Amour, of which 4,000 miles from Moscow to Wkutsh are in operation, and that she has granted to Mr. P. M. Collins of New York a concession for thirty-three years, to extend this line up to and across Behring Straits, and then through her American territories to the frontier of the British possessions, a distance in all of 4,500 miles, that the British Government have granted a similar privilege down the northern frontier of the United States, and that an application is now pending in the Washington Congress for like permission through that country, thus connecting the whole telegraphic system of America. The Chamber unanimously resolved to memoralize the President and both Houses of Congress in favour of the undertaking. The full completion of the project may, it is alleged, be expected within three years. The total distance overland by way of Behring Straits, which are only 39 miles wide and 160 feet in depth, will be about 13,000 miles; and it is asserted that messages have been repeatedly sent during the present year from Boston to San Francisco, a distance of 3,000 miles in two minutes.

THE EGHAM RAILWAY ACCIDENT.—The jury, after a deliberation of nearly three hours and a half, returned a verdict of "Manslaughter against Thomas Lee, the driver, and John Trainer, the fireman of the Milo engine, attached to the second train, in having caused the deaths of William Winfield, Robert Wilkie, Edwin Halls, William Coppard, and Joseph Clegg; and the Jury consider that John Renshaw, the first guard, and John Dempsey, the second guard, laboured under great disadvantage owing to the mismanagement of the company—firstly, in not having a turn-table, thereby causing the trains to be sent out tender first, so that there was no use of the communicator; secondly, the want of telegraphic communication; and thirdly, the want of knowledge of the stopping of the trains, the first being at Egham and the second at Staines.

NEW SOUTH WALES.—The only telegraphic works at present in progress in this colony are three branch lines, which are being carried out under the arrangement with the residents in the various districts, that the Government shall receive £5 per cent. on the outlay. On the line from Braidwood to Queenbeyan, a length of thirteen miles have been cleared, the holes for the posts have been sunk for the distance of fifteen miles, the posts are all erected on the line from Deniliquin to Hay, and fifteen miles of wires are stretched. The line from Wellington to Dubbo has been commenced. The estimates for 1864 being at length passed, tenders will shortly be called for the new lines for which money has been voted. Those consist of extensions from Mudgee to Murrurundi, and from Braidwood to Arulen, and the extension of the line to Cooma.—*Herald.*

FISHING BY ELECTRIC LIGHT.—A first attempt was made to fish by electric light a short time since at Dunkirk. The light was supplied by a pile on Bunsen's principle, composed of about fifty elements, and it succeeded tolerably well, but the employment of the pile was attended with much inconvenience. It was then determined to repeat the attempt with a magneto-electric machine. The new experiments tried at Dunkirk and Ostend had a double object—first, to prove how the light produced by the machine would act under water; and second, to discover the effect the light would produce on the fish. The first object was completely accomplished, and it is now demonstrated that magneto-electric machines and the light they produce are applicable to all submarine works. In fact, this light was constant at 180 feet under water, and it extended over a large surface. The machine, nevertheless, was placed at a distance of more than 300 feet from the regulator of the electric light. The glass sides of the lantern remained perfectly transparent, and the quantity of coal consumed was less than if it were in the open air.

THE SPEZZIA AND CORSICA SUBMARINE CABLE.—The steamer Fanny Lambert, Captain Christopher, arrived at Malta on the 25th inst. from Genoa with Mr. John Temple, engineer; Mr. Henry Saunders, electrician to Messrs. Glass, Elliot, & Co.; and a staff of workmen, having been away for a month repairing the submarine telegraph cable between Spezzia and Sardinia and Cape Corso, in Corsica. As this is one of the very earliest deep-water cables, having been laid in 1854 in over 250 fathoms of water, and as it has worked without the slightest interruption up to the present time, some information as to its condition will be interesting. We understand that close to the shore, within half a mile, the cable was much chafed and worn on the Cape Corso (Corsica) side, but after that it proved to be in excellent condition for about twelve miles out, where, after passing over 90 fathoms depth of water, it suddenly shoaled to 60 fathoms, and the cable having the outer protecting wires completely chafed off it broke. The soundings showed that a reef of sharp rocks extended in a northerly direction. The cable was grappled outside of this reef in about 80 fathoms of water, about three miles nearer Spezzia than where it broke, and as signals were then good to Spezzia the cable was relaid to the Corsica shore again clear of the rocky reef, and communication re-established. The cable is what is termed a heavy cable, as it weighs ten tons to the mile, the protecting wires being twelve No. 1 wires, and although it has been laid ten years, the outer wires show a very slight deterioration, the decay and oxidization being hardly perceptible, excepting very near the shore. The gutta-percha insulating the copper conductor is in a perfect state of preservation, not having suffered in the least, and the hemp bed for the outer wires has the tar still fresh in it. Had the cable been originally laid clear of the reef, as it now is, it would not have suffered any interruption, and it is very encouraging to the cause of submarine telegraphy to know that the cables are so permanent and durable as this cable has proved.

TELEGRAPHIC SCHEMES.—Mr. Secretary Seward, being called upon to state to a committee of the Senate his views upon Mr. Collins's project for a telegraphic line connecting the Russian systems of telegraphs with those of America, reports that throughout that gentleman's negotiations with the Russian and British Governments for leave to pass through their American possessions he has been acting under the instructions of the American Government, and that his application to Congress for a right of way across the public lands and the use of a national vessel is reasonable. Mr. Seward proceeds to say that the line which the Russian Government is constructing, or has undertaken to construct, from St. Petersburg to the mouth of the Amoor, is but a small part of the stupendous work which the Emperor has begun. His Imperial Majesty's design embraces also a telegraphic wire from the mouth of the Amoor, over the islands of Sakhaliu and Jerro to Jeddo; also, from the Amoor, along the banks of the Usuri, to Viadi Vostok on the coast of Tartary, Viadi Vostok being selected by the Emperor for his naval station on the Pacific coast; also a wire from the Irkoutsk telegraphic line, though the vast territory of the Mongols to Pekin; and American citizens in China are soliciting, with good prospect of success, permission from the Chinese Government to extend this line to Nankin, Shanghai, Amoy, and Canton. Further, the Russian scheme comprises a telegraphic wire from the main Continental-Russian line at Omsk, near the southern boundary of Asiatic Russia, through Mongolia, China, Turkestan, Bokhara, and Cabool, to meet the telegraphic system of India in the Punjaub, and connect it with Europe; and also a wire from Kazan on the main central Russian line, passing along the shore of the Caspian Sea to Teheran and along the banks of the Euphrates to the Persian Gulf, there to be connected with the telegraph system of India. Mr. Seward, however, confines his remarks chiefly to the line immediately in question, connecting America with Russia through Behring's Straits. He submits to the Senate that it is impossible to over-estimate the direct effect of such works in the development of the resources of the American States, or to assign limits to the increase of national influence which must result from such new facilities for extending throughout the world American ideas and principles of public and private economy, politics, morals, philosophy, and religion. The telegraphic wire is at present, he says, timidly employed and clumsily handled, with a very imperfect knowledge of the fulness of the power which resides in it; he anticipates that telegraphic communication will become far more practically effective. He trusts that an Atlantic line will soon connect Cape Clear and Cape Race, thus completing with the proposed line through Russia a telegraphic circuit round the earth between 42 and 65 degrees north latitude; but he holds it to be certain that the great interest of society will at a very early period require more than one, and more than even two trans-oceanic world-encircling telegraphs.

THE ELECTRIC AND INTERNATIONAL TELEGRAPH COMPANY.—EXPERIMENTS ON THE PNEUMATIC SYSTEM.—On Wednesday, the 22nd ult., several important experiments in telegraphy were made with an apparatus constructed on the pneumatic system at the offices of the Electric and International Telegraph Company in Castle-street. A number of influential gentlemen were present, and the proceedings were watched with much interest. The visitors were conducted through the different rooms of the establishment by Mr. Whittingham, the manager to the company, and the mode in which it was proposed to work the apparatus was lucidly explained by Mr. C. F. Varley, the inventor. Owing to the increase of telegraph business at the various stations of the company in Liverpool, and their central station in Castle-street, they resolved upon connecting them by means of an apparatus known as the pneumatic system. On the basement of the building in Castle-street an engine of about one-horse power has been fixed, working an exhaust air-pump, and also a compressed air cylinder. These two pumps during the busier hours of the day are continually forcing air into the vessel called the compressed air chamber, while the other is continually exhausting a similar chamber known as the vacuum cylinder. The dimensions of these two reservoirs of power are 4 feet in diameter and 10 feet in length. There are valves attached to the chambers, by which means the vacuum reaches 20-inch air, but is limited to that amount. The compressed air valve is weighted to blow off at 11 lbs. The two chambers are connected with the instrument-room on the first floor by means of lead pipes two inches in diameter. In this room there are two valves of novel construction, which are destined for sending or receiving messages to or from the company's stations at the Royal Exchange or in Water-street. Electricity performs a subordinate part in this operation, and by its aid bells are rung at the different stations, and the necessary signals connected in a moment for the transmission of the messages. On the Royal Exchange officials wishing to send a message to Castle-street, the clerk rings the bell once, when another clerk in Castle-street, by simply pressing down a little button connected with the exhausted chamber, sets in operation the whole of the apparatus necessary for transmitting the message. The first action is to close up the valve; the second to open a communication between the pneumatic pipe which reaches from the Royal Exchange to the exhaust chamber in Castle-street. The pressure of air being thus taken from the tube, the air rushes in at the Royal Exchange end, and carries the little piston containing the message through the pipe to Castle-street. On its arrival at Castle-street, by a simple self-acting contrivance the communication between the exhaust chamber and the pneumatic pipe is severed, the vacuum destroyed, and the valve opened, when the carrier falls on to a counter prepared to receive it. The distance between these stations is about 300 yards, and the time occupied by the little piston containing the message coming through was found by experiment to be 16 seconds—the rough estimate of time being about 40 miles an hour. The whole of the apparatus is self-acting, and the moment the signal is given the clerk in attendance has but to touch a button, when the compressed air or the vacuum is made to open or close on the necessary valves, and to transmit the despatch. To send the message back from Castle-street to the Exchange or Water-street buildings the compressed air chamber is brought into requisition. The message is first of all put into the pipe, and by pressing a button labelled "send," the compressed air is made by the self-acting apparatus, first of all, to close the end of the tube, and, having closed it, to open a communication between the large compressed air chamber and the pneumatic pipe, when the carrier containing the message is blown to its destination. The moment it arrives the clerk gives two strokes to the electric bell, and the clerk in attendance at the Castle-street station immediately presses a third button

labelled "receive," when the vacuum chamber is once more called into requisition, and cuts off all communication between the pipe and the air chamber. In a short time, however, this operation by the clerk will be dispensed with, as it is intended to make electricity perform it, and the apparatus will then be entirely self-acting. We may state that the pneumatic pipes have been worked by the Electric Telegraph Company in London for the last ten years, and that the messages have invariably been conveyed by atmospheric pressure—that is to say, by a vacuum. Two tubes were necessary in order to send messages through the pipe in opposite directions—the one to convey the messages, the second to convey the vacuum or force to the distant station for taking them back again. In the apparatus, however, in Castle-street, compressed air is used for the purpose of sending the messages back, so as to obviate the conveying of vacuum to the second pipe to a distant station; greater speed and certainty are, too, obtained in the delivery of the message, as the air has to travel a shorter distance—that is, through one tube—and any amount of pressure may be obtained by means of compressed air. In the present case 11lbs. per inch pressure is used, but greater distances would be reached by a higher pressure, were such necessary. The present pipes are 1½ inch in diameter, and three-quarters of a mile in length, and the period occupied in sending a message through these distances varies from 70 to 90 seconds. The new system of telegraphy is being extended all over London by the Pneumatic Despatch Company, who are laying down pipes 4 feet 6 inches in diameter, so as to carry the mails between the Post-office and the Euston terminus. The great advantage of the new system is that it enables the Electric Telegraph Company to cope with the increasing traffic, to perform the service more expeditiously and more cheaply, and lastly, to avoid the errors hitherto consequent upon the transmission of messages between the central and out stations. The apparatus altogether is remarkable for its ingenious and practical character, and worthy of its able inventor, Mr. C. F. Varley. The experiments made on Wednesday were eminently successful. In the evening the following gentlemen dined together at the Adelphi Hotel:—Mr. Cromwell F. Varley, electrician and engineer of the Electric Telegraph Company, in the chair; Mr. Barber, chairman of the Great Eastern Ship Company; Mr. Boult, Mr. Whittingham, local manager of the Electric Telegraph Company; Mr. Thomas Court, Mr. L. H. Parr, Mr. George Newman, Mr. J. Muirhead (of London), &c. The cloth having been removed, the loyal toasts were given, and the chairman, in proposing "The Health of Mr. Barber," delivered a most interesting address, in the course of which he referred to the great influence which science had had in civilising tribes of mankind who had hitherto lived in a savage state. The discoveries of science had enabled steam to be produced from coal, and from this had followed steam navigation and railway communication. The application of electricity to the transmission of telegraphic messages had not been less important. It was an interesting fact that the great telegraphic system in the British possessions in India was about to be connected with the enormous telegraphic system of Europe through Teheran, the capital of Persia, and the wilds of Siberia. The whole of the Indian communication would ultimately pass through Turkey, viâ Bagdad, but at present there was a link wanting in the chain, owing to the hostility of the tribes between Bagdad and Bussorah, who had frequently destroyed the telegraph. Since English officers had commenced negotiations there was every probability of the confidence so unfortunately forfeited by the Turkish authorities being restored, and an early completion of the line was anticipated. The Russian Government had already extended her telegraph as far as Irkoutsk, in Siberia, on the frontier of China, and at no very distant date they might anticipate that America would be connected with Europe through those channels. But prior to that date there was every reason to hope that the direct Atlantic route between Newfoundland and Valentia would be successfully established. As an instance of what might be anticipated in future, the following would enable an idea to be formed: By the automatic relays, established all over the European system of telegraphic communication, the various lines were linked together; a fresh power was automatically picked up at various transmitting stations, and direct communication was established between these points, distant 6,000 miles, without the intervention of any human transmission. On the completion of a message from Irkoutsk to London, the answer was commenced in London within three seconds of the completion of the message to London. On a recent occasion the director-general of telegraphs in Russia, General Guerbard, sent to him (the chairman) a message on a Sunday morning from Irkoutsk, which was handed the same day to Mr. Cyrus Field, on board the Persia, at Queenstown. This message was published in San Francisco in ten days and a-half from the date when it left Irkoutsk, of which nine days and a-half were occupied in carrying the message from Queenstown to New York. The total distance over which the message was transmitted was about 9,000 miles, 7,000 of which occupied but twenty-four hours. Thirty years ago any person who had ventured to say that a message would be sent from London to Liverpool in five minutes would have been looked upon as a madman; and yet, in much less time, the frontier of China was able to communicate with any station in Europe. Even in the uncivilised country of Persia the telegraph had extended itself; and it was a most significant fact that the great English system in India would, within a very few days, be in communication with that enormous European system of telegraph through the hitherto supposed uncivilised country of Persia, and the scarcely known regions of Siberia. It was also a remarkable fact that one of the most successful telegraphic systems was that between New York and San Francisco. It was carried through savage Indian territory, and across snow-capped mountains which had hitherto been considered almost inaccessible. The time occupied in carrying a mail from California to New York was six days, and so important was this communication that the projectors were remunerated during the first year by a dividend of ninety-six per cent. It was not uncommon for the news which appeared in the New York journals to re-appear on the same day (owing to the difference in latitude) in the San Francisco journals. Recent events had shown the importance of direct communication between England and America. Already the telegraph extended from New York to Newfoundland, and from London to Valentia, and the only link not completed was that of 1,640 miles. When this was completed there would be uninterrupted communication between California and Mexico in the west, and Irkoutsk in the far east. The Great Eastern was the only ship capable of laying the cable to complete this important chain. It had afforded him (the chairman) great and unexpected pleasure to meet with Mr. Barber, the representative of the ship, and he thought it right to mention the advantageous terms upon which that ship had been lent for this enterprise. Her profits were entirely identified with the success of the undertaking. The chairman concluded by proposing, "Success to the Atlantic Cable and the Great Eastern Steamship, coupling with the toast the name of Mr. Barber." The toast was heartily received. Mr. Barber, in responding, observed that he trusted that the enterprise in contemplation would enable the Great Eastern to prove a scientific success, though hitherto she had not been a commercial one. The terms of the present engagement were highly satisfactory, and he believed the time was not far distant when the anticipations formed of the great ship would be realised. Several other toasts were proposed, and allusion was made by subsequent speakers to the fact that Liverpool was the only town in the kingdom, besides London, in which the Pneumatic Company had gone to the expense of introducing the pneumatic system. "The Healths of Mr. Newman and Mr. Whittingham" were proposed and responded to, and the proceedings shortly afterwards terminated.—[We quote the above from the *Liverpool Daily Post*, and do not hold ourselves responsible for the statements contained therein.—ED. *T. J.*]

MISCELLANEA.

QUICK WORK.—The Siberian telegraph line is working to Queenstown, Ireland, from Irkoutsk, Siberia, a distance of 6,500 miles. A despatch was transmitted the whole distance in two hours, a great feat, making a fair allowance for gain in apparent time.

SLEEP.—Women require more sleep than men, and farmers less than those engaged in any other occupation. Editors, reporters, printers, and telegraph operators need no sleep at all. Lawyers can sleep as much as they choose—it will keep them out of mischief.

THE TELEGRAPH AND THE PRESS.—I proceeded to a suite of rooms occupied by the sub-editor and the principal reporters. In the outermost of these rooms is arranged the electric telegraph apparatus—three round discs with finger-stops sticking out from them like concertina keys, and a needle pointing to alphabetic letters on the surface of the dial. One of these dials corresponds with the House of Commons, another with Mr. Reuter's telegraph-office, the third with the private residence of the conductor of my journal, who is thus made acquainted with any important news which may transpire before he arrives at, or after he leaves, the office. The electric telegraph—an enormous boon to all newspaper men—is specially beneficial to the sub-editor; by its aid he can place before the expectant leader writer the summary of the great speech in a debate, or the momentous telegram which is to furnish the theme for triumphant jubilee or virtuous indignation; by its aid he can "make up" the paper—that is, see exactly how much composed matter will have to be left "standing over," for the tinkling of the bell announces a message from the head of the reporting staff in the House to the effect, "House up—half a col. to come." Sometimes—very rarely—wires get crossed, or otherwise out of gear, and strange messages relating to misdelivered firkins of butter, or marital excuses for not coming home to dinner, arrive at the office of my journal. The sub-editor has a story how, after having twice given the signal to a West-end office which Mr. Reuter then had, he received a pathetic remonstrance from some evidently recently-awakened maiden, "Please not to ring again till I slip on my gown!" On the sub-editor's table lie the weapons of his order—a gigantic pair of scissors, with which he is rapidly extracting the pith from the pile of "flimsy" copy supplied by the aid of the manifold writer and tissue paper by those inferior reporters known as penny-a-liners, and a pot of gum, with which he fits the disjointed bits together; here also are proofs innumerable in long slips; red, blue, and yellow envelopes, with the name of my journal printed on them in large letters—envelopes which have contained the lucubrations of the foreign and provincial correspondents; an inkstand large enough to bathe in; a red chalk pencil like the bowsprit of a ship; and two or three villainous-looking pens. At another table, a gentleman gorgeous in white waistcoat and cutaway coat is writing an account of a fancy fair at which he has been present; printers, messengers, boys, keep rushing in, asking questions and delivering messages, but they disturb neither of the occupants of the room. The fancy fair gentleman never raises his eyes from his paper, while amid all the cross-questioning to which he is subjected, the sub-editor's scissors still snip calmly on.—*All the Year Round.*

Iron becoming Hot by Stretching.—In a recent discussion on testing chain cables, Mr. Gladstone stated that he had had great experience in the matter, and had observed that when the iron begins to stretch the temperature rises, becoming so hot before the link parts, that the hand when brought in contact with it cannot bear the heat.

Temperatures at which Metals Boil.—These have been hitherto determined by means of an air pyrometer, but M. Becquerel has adopted another method for their determination. The instrument he employs is a thermo-electric pile, and with it he found that the following metals boil at the following degrees Fahrenheit:—Cadmium, 1,328; zinc, 1,688; silver, 1,681; gold, 1,879; palladium, 2,517; platinum, 2,690. It is of some importance to state that certain of these figures are lower than those obtained by M. Becquerel, when using the air pyrometer.

How to Work.—Cheerfulness gives elasticity to the spirit. Spectres fly before it; difficulties cause no despair, for they are encountered with hope, and the mind acquires that happy disposition to improve opportunities which rarely fails of success. The fervent spirit is always a healthy and happy spirit, working cheerfully itself, and stimulating others to work. It confers a dignity in even the most ordinary occupations. The most effective work, also, is always the full-hearted work—that which passes through the hands or the head of him whose heart is glad. Hume was accustomed to say that he would rather possess a cheerful disposition, inclined always to look at the bright side of things, than with a gloomy mind to be master of an estate of ten thousand a year.

A Yankee "Notion."—The following humourous lines appear in a New Year's Address of the carrier of the *Scientific American*. Our friends across the water have either very inadequate powers of discrimination between *meum* and *tuum*, or they have allowed their Muse unlimited scope in the region of fancy. Poets are generally permitted to deviate from exactitude, where no vital consequences are involved; but the carrier of our trans-Atlantic contemporary, in this instance, has made sad havoc of facts:—

"Now, how shall I, the humblest of all men,
Describe the telegraph with my poor pen?
My 'lines' are not of wire, but lines of ink;
Yet, if you should *ink-wire* who made that link
Which joins the earth's most opposite extremes,
Annihilating time and space, it seems
One answer only I could give. 'Tis plain
That Samuel Finley Breese Morse did attain
Perfection in the telegraphic art;
Making men's words, like lightning's flashes, dart
A thousand miles within a moment's space;
Uniting nations—joining race with race!
Through the dark storm-cloud good old Franklin saw
A glimpse of God's great skyward-written law!
By simple means—a kite and string and key—
He proved that lightning hath identity
With the electric fluid, which, it seems,
He drew from sky to earth in brilliant streams.
By electricity—that wondrous fire—
The mind of man is made to run on wire!
Mind, unlike matter, cannot be defined.
Would you know what is *matter?* Never *mind!*
Morse built in year 'eighteen and forty-four,'
Straight between Washington and Baltimore,
A 'line'—the first in the United States—
And did much business, spite of heavy rates,
When through deep rivers Morse found he could talk,
A short aquatic line quite near New York
His hands constructed; this was a success,
Although a small affair; but yet, I guess,
In Morse's eye a 'cable' submarine,
Beneath the great Atlantic was then seen.
'Oh!' cries some saucy youth, 'I'd like to spy
The man who had a cable *in his eye!*'
Years afterwards occurred a great event:
A British Queen and Yankee President
Congratulations sent beneath the sea;
But Neptune would not with the 'wire' agree.
Said he: 'This telegraphic talk I ban!
No President 'or any other man'
Shall flirt with females *under water*. Hence
He cut the 'cable,' but we can't dispense
With such a 'bond of brotherhood.' I hope
That ('if it please the pigs' or 'teaze the Pope')
Before next New Year's Day, we shall be tied
To England by a wire, just like a bride
And bridegroom by a ring. That magic charm
Shall guard both nations from each other's harm.
But not alone to Morse we look for news;
There's Bain and House, and (later still) there's Hughes.
Each of these telegraph inventors can
Claim praise for ingenuity. The man,
However, whom Fame doth the most indorse—
The people's favourite messenger—is Morse."

PATENTS.

APPLICATIONS FOR LETTERS PATENT.

1538. W. J. Pughsley, improvements in obtaining sulphuric acid from the refuse "pickle" used in tin-plate works, and also from sulphate of iron or green copperas.
1565. J. D. Adams, improvements in electrical communicators.
1577. Improved machinery or apparatus for vulcanizing india-rubber, which machinery or apparatus is peculiarly adapted for vulcanizing by the cold process or without the application of heat.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

680. W. A. von Kanig, improvements in railway telegraphs and signals, and also in the permanent way and carriages for preventing railway accidents.
1386. W. Clark, improvements in electro-magnetic and magneto-electric apparatus, and their application as a stationary or locomotive driving power.—A communication.
1412. H. A. Bonneville, improvements in telegraphic printing apparatus.
1458. J. McElroy, improvements in electro-telegraphic apparatus, and in instruments for preparing the transmission of electric telegrams.

NOTICES TO PROCEED.

454. E. A. Cotelle, an apparatus for concentrating and distilling sulphuric and other acids, and all solutions in general.

PATENTS SEALED.

833. W. E. Newton, improvements in electric or telegraphic conductors.—A communication.

PATENTS WHICH HAVE BECOME VOID.

1503. J. A. Callaud, improvements in the construction of electrical piles.
1512. R. Jobson and C. F. Varley, improvements in posts or supports for telegraph wires.
1567. W. E. Newton, improvements in electro-magnetic engines.

PATENTS ON WHICH THE STAMP DUTY OF ONE HUNDRED POUNDS HAS BEEN PAID, AND DATES OF THEIR PRODUCTION FOR CERTIFICATE.

1830. W. Pole, improved means for supporting telegraph wires.—30th June, 1857.

PRICES CURRENT OF INSULATING MATERIAL.

TO CORRESPONDENTS.

Investigator.—The galvano-meter employed consisted of 30·500 coils of wire, $\frac{1}{570}$ of an inch in diameter, most efficiently covered with silk by Mr. Campion. The needles (not astatic) were suspended by an unspun silk thread. The remaining parts were constructed by Mr. Izant.

As information respecting Improvements, Extension of Lines, and Progress of New Undertakings will at all times be most acceptable, we hope that our readers will kindly render us assistance in our efforts to establish a Journal worthy in all respects of the great interest it seeks to represent, by furnishing us with brief notices of events and occurrences in connection with Telegraphy.

The *Telegraphic Journal* can be had of Messrs. Smith & Co., Strand; Messrs. Dawson & Co., Cannon-street, E.C.; Messrs. Kent & Co., Paternoster-row, London. Messrs. Heywood & Co., Manchester; at the various railway stations; and of all news-agents, &c., &c.; or it can be supplied, if preferred, direct from the Office on the following terms:—

AN INSURANCE COMPANY'S PROTEST AGAINST ELECTRICAL OPERATIONS.

"MOVE ON" is a recommendation that might be given to others than itinerant vendors of edibles. We know of people who are sadly behind the age. They have not yet realized the advantages of the railway system, and prefer the light of a "dip" to gas illumination. If they have adopted any improvements effected by human ingenuity since their childhood it has been owing to external pressure or from sheer necessity. They are constrained to advance, but it is always slowly, and in the rear of their contemporaries. In business relations it should be otherwise. We commend the exercise of caution in commercial transactions, but most strenuously protest against a spirit of obstructiveness manifested occasionally in spheres where we had hoped to find a disposition to encourage the arts, sciences, and manufactures. In these days of cheap literature, when every possible means have been employed to raise the standard of middle class education, and to popularise science, no palliation can be offered for an offence against the teachings and experience of the *savans* of Europe by the directory of an association depending in a great measure upon the patronage of the public.

It will be within the recollection of our readers that on the 11th ultimo a *soirée*, in connection with the Royal Astronomical Society, was held at Willis's Rooms, under the able presidency of Mr. Warren De la Rue. Concerning this meeting an almost incredible story is narrated in a contemporary, which shows the petty annoyances to which men of science are subjected at the hands of others, whose social status would lead us to expect better things from them. Mr. De la Rue says:—

"On Friday, the 10th June, during the preparation of Willis's Rooms for the reception on the following day, the proprietors informed me that they could not permit electrical experiments, as their insurance office had given them notice that the Company would not hold themselves liable for damage by fire during the continuance of electrical apparatus in the building. Not wishing to forego the exhibition of experiments for which extensive preparations had been made, I called on Saturday, the 11th, on the secretary of the office, who received me very courteously, and listened patiently to my explanation, but declined to remove the veto which had been issued or to grant a special insurance, for which I would have paid. Under these circumstances I addressed myself to the Sun Insurance Office, where I had already insured the articles entrusted to me for exhibition, and effected an insurance for £20,000 on the buildings and contents. Although the expense was not considerable, I was put to much personal inconvenience at a time I could ill be spared from the superintendence of the arrangements."

We are not surprised at the course pursued by the proprietors of Willis's Rooms—most men of business would have acted likewise in a similar situation; but we confess to no small degree of astonishment that the Royal Exchange Fire Insurance Company should repudiate its liability without giving good and sufficient reason for such a proceeding. It would be interesting to know the precise objections entertained by this Company to electrical apparatus. Many persons unacquainted with the interests we represent would be led to suppose, from the determination of the Company not to remove the veto on remonstrance, or to issue a special policy of insurance on a very equitable condition, that electrical operations are generally attended with disastrous results; but this supposition we know to be unfounded. There is not even a tradition of importance current in insurance circles relative to danger to be apprehended from this class of risks, for most of the buildings in which our great telegraph works are carried on are insured at ordinary rates. The circumstance that the multiplication of electrical apparatus at the top of house property in London and other large towns averts destructive catastrophes from lightning appears to have escaped the attention of the sapient Board of Directors. The presence of "batteries," the emission of "sparks," the glare of an intense "light," the "combustion" of charcoal points, and the possibility of metal being "fused" by electricity in one building must have been "shocking" in contemplation! The experiments proposed were not of a dangerous character. It was not intended to raze the walls of the building with a torpedo, but simply to exhibit the electric light. Had the Directors visited the Royal Institution, or any chemist's laboratory, they would have found far more terrible instruments in full operation than those placed on view in Willis's Rooms "for one night only;" and had they satisfied themselves that additional risks were being incurred on this occasion, and demanded a proportional premium, we should have been spared the painful duty of adverting to their folly and obstinacy. It is a difficult matter to deal with Boards; as one of our satirists has remarked, "they have neither souls to be saved nor bodies to be kicked." The managers of large commercial undertakings are generally shrewd men, well posted in the details of the business in which they engage. Not so in the case under consideration. The Directors of the Royal Exchange Fire Insurance Company appear to be unable to discriminate between cause and effect—between an instrument to be employed and the result to be attained by its operation. Their liability was repudiated not on account of approximate danger, but in consequence of the existence of electrical apparatus in the building insured in their office. The absurdity of the objection hardly merits serious consideration. It is frivolous and vexatious in the extreme, and "fit only for a 'point' in the wildest pantomime."

INDIA-RUBBER COVERED CABLES.

IT will be remembered that Sir W. O'Shaughnessy ordered for the Indian Government a length of twenty miles of copper-wire, coated with india-rubber by Messrs. Hall & Wells, and sheathed by Mr. Henley with an outer covering of galvanised iron wires. The conductor was a strand of seven wires, weighing 270 lbs., the caoutchouc weighing from 165 lbs. to 170 lbs. per statute mile.

This cable has been erroneously referred to as being used in the Persian Gulf. It was intended to cross an inlet upon the Mekran coast, forming part of the Guadur and Kurrachee line, but the line was completed, by means of an overground telegraph, before the cable arrived, and it was consequently coiled, under cover, in the hold of the Hyderabad flat, in Kurrachee harbour.

On the arrival of Colonel Stewart, at Kurrachee, in the Coromandel, on the 25th January last, it was determined to send five miles of it to Mussendom, to be used in a separate circuit, in order to test its utility, and it was accordingly sent there, and coiled under water in Elphinstone's Inlet.

When the station was removed from the mainland to Elphin-

stone Island it was decided to employ part of it in uniting the island to the mainland. On testing it, however, it was found defective, the caoutchouc showing signs of tackiness. After cutting it into four sections, all but one of which were very faulty, a length of thirteen hundred yards was picked out with sufficiently good insulation for use. This was laid from the Clyde gunboat, on the 29th February, between the land and the newly-established station on the island. After working for a short time the insulation began to fail rapidly, and on the 14th March it was found necessary to lay a length of the regular Persian Gulf cable to supply its place. On the 16th the caoutchouc-covered cable was taken up, to examine into the cause of failure, when the insulator was found to have become very soft, and, on exposure to the air, became of the consistence of treacle; very similar, in fact, to the state of the length of rubber-covered cable laid from Manora Point, near Kurrachee, in 1860, which was picked up and examined by Mr. Latimer Clark, in 1862.

It would appear that something is still wanting in caoutchouc-covered cables, to ensure their permanency. This is much to be regretted, for, could the quality be attained, the high insulating property of the material, and its low inductive capacity, would doubtless lead to a very extended use of india-rubber in submarine telegraphy.

FORCE AND FORM.

CONTRIBUTED BY BLANCO MOUGREVE.

FORMERLY scientific men, in writing of matter, divided it into two sorts, ponderable and imponderable. The imponderables were heat, light, electricity, and magnetism. They have now come to consider these imponderables as force, and not matter. I wonder what the essential properties of matter are? We have seen a great deal that has been written, and heard a great deal that has been said on this subject. It may have been to good purpose, or it may not. Also we have heard a great deal said against all such vain speculations, a bottling up of moonshine —by the way, cannot moonshine be bottled up? I believe it can; though moonshine is not matter, *selon nos savants*. But would it not be a desirable thing to know what we mean when we say *matter?* doubtless, and also what we mean when we say force—I beg pardon, *energy?* that is the fashionable word as I believe: but habit is so strong with me.

It does not appear to me that it would be a very difficult task to separate the accidental from the necessary properties of all those that we know of both matter and force: let us try. Matter first. To the sight: colour and shape. Colour is not essential, for matter may be colourless. Shape is infinite, regular, or irregular, and matter must of necessity have some shape; seeing that matter is infinite and must be bounded by surfaces; but the general expression of shape is form; therefore form is essential.

To the touch: hard, soft, or unyielding and yielding, elastic, nonelastic, rough, smooth, and hot and cold, also shape or form, and, together with all these, resistance. Of these, form and resistance are the only generals, for each of the others can be dispensed with in turn, but these never. Therefore, form again is essential, and to it is added resistance.

To the smell: there can be no smelling without effluvia; but what is effluvia. Philosophers say they are the finest and most volatile parts of matter, and though they cannot be perceived by sight or touch, yet reason shows that without form and resistance they are not even conceivable. But has all matter scent? Our experience says no, and our smell is no further concerned; but whether all matter has effluvia, or which is the same thing, has a sphere of volatile particles, is another affair, and does not touch us here.

To the taste: some forms of matter are said to be tasteless; therefore taste is not essential.

To the hearing: hearing is the effect of the tremor, or gyration of the air; therefore is some form of the motion of matter, and from it no essential property of matter is perceived, or derivable.

Of all the properties of matter perceivable by our senses, form and resistance, it appears by this induction, are the only essentials; that is, matter is a somewhat which is cognizable to our senses as a form having resistance. Form is the bounding surfaces of a thing, which circumscribes it and separates it from every other thing: and resistance, what is it? It appears to be that power, which prevents matter being torn to pieces, and also prevents its compression beyond a certain limit. The one is called attraction, the other repulsion; but these are two manifestations of force or energy.

What then do we mean by matter? A form which is maintained such by an inherent force or energy, or simply force in a form. Now, I think, we have fairly come at this conclusion. However, if experience teaches anything to the contrary thereof, those who have such experience are hereby desired to declare it.

But is not that a wild conclusion? Still we take our senses with us, do we not? and in fact, do not take a step without their sanction. They may deceive us? Possibly. But everybody's senses will not deceive everybody at the same time; therefore the few in error can be corrected by the many not in error. True we cannot back up our conclusion by a host of authorities; but we can bring three that stand for something, and two of them at least I know to be common-sense matter-of-fact men, who have seldom soared into the regions of imagination: they are Swedenborg, Boscovich, and Faraday.

The first was a mystic, was he? Well, you say that because you know nothing of him. Ask Charles the Twelfth, and he will tell you, that he was his right hand of science; he took his ships across fourteen miles of dry land, he built him docks, he smelted him iron, he discovered for him and the whole world a new method of calculating longitude, which is partially in use still, after more than a century, and he alone has given the true theory of the magnet; I would not attempt even barely to name what he did for the arts and for science. And the last-named—there is no need to say anything of him; he is amongst us, and we all know him.

This is his reasoning on the subject; first having referred to the generally-received notion of an atom, as a little unchangeable, impenetrable piece of matter, with an atmosphere of force grouped around it:—"If the view of the constitution of matter already referred to be assumed to be correct, and I may be allowed to speak of the particles of matter and of the spaces between them as two different things, then space must be taken as the only continuous part; for the particles are considered as separated by spaces from each other. Space will permeate all masses of matter in every direction, like a net, except that in place of meshes it will form cells, isolating each atom from its neighbours, and itself only being continuous. Then take the case of a piece of shellac, a non-conductor, and it would appear at once, from such a view of its atomic constitution, that space is an insulator, for if it were a conductor the shellac would not insulate, whatever might be the relation as to conducting power of its material atoms; the space would be like a fine metallic web penetrating it in every direction. . .

"Next take the case of a metal platinum or potassium constituted according to the atomic theory in the same manner:— The metal is a conductor; but how can this be except space be a conductor, for it is the only continuous part of the metal, and the atoms not only do not touch (by the theory) but, as we shall see presently, must be assumed to be a considerable way apart. Space therefore must be a conductor. . . . . . .

But if space be a conductor, how then can shellac, sulphur,

&c., insulate? For space permeates them in every direction. Or if space be an insulator, how can a metal or other similar body conduct?

". . . . . . . Any ground of reasoning which tends to such conclusions as these, must in itself be false. If we must assume at all, as indeed in a branch of knowledge like the present we can hardly help it, then the safest course appears to be to assume as little as possible, and in that respect the atoms of Boscovich* appear to me to have a great advantage over the usual notion. His atoms, if I understand them aright, are mere centres of force or powers, not particles of matter, in which the powers themselves reside. If in the ordinary view of atoms, we call them particles of matter, away from the powers, *a*, and the system of powers or forces in and around it, *m*, then in Boscovich's theory *a* dissolves or is a mere mathematical point. . . . .†"

Referring to the differences between Boscovich's, and the ordinary theories, he says:—"With the latter, atoms is a mass of matter consisting of atoms and intervening space; with the former atoms, matter is everywhere present, and there is no intervening spaces unoccupied by it. . . . . Hence matter will be continuous throughout." But we refer the reader to the *Philosophical Magazine*, for his reasonings in full.

Now let us strive to ascertain what we mean precisely by the word force or energy.

To our senses there is but matter and its changes. We have seen what properties are essential to the existence of matter, to our senses, and within these is included force, as essential to matter; but though any mass of matter must have within it an inherent force, it may also have force acting upon it from without. This is accidental; but it is a manifestation of force, and to the senses is simply change of place or state.

To the sight. It is motion, or change of colour or form, that is change of place or state.

To the touch. Change of form, or of surface, or of temperature, or consistency: as from solid to liquid.

To the smell. Change of scents, or change of degrees of the same scent.

To the taste. The same as to flavours.

To the hearing. Change of sounds as to quality, or as to degrees.

Therefore as to force, *change* is the only essential which is perceivable by our senses, and force is a necessary inference of the intellect, as a power that produces change, seeing that no change can be conceived to produce itself, no, not even if it were a *thing*, for that would be supposing it to exist before it did exist, so that it might exist. This force then is that inscrutable life which runs through all things, from stones and earth through plants, animals, and man, whereof form is the body. Yes, life of even stones and dirt! The power to be and to do. Can anything exist without it? Take the lowest form. Can anything exist without attraction of cohesion? A quasi-passive force, whereof the active is chemical affinity, from which we mount to organic, or vegetative, thence to animal, and finally to man, and to each by insensible gradations; but this is a wide subject and leads away from our present enquiry. It is well then to know what we mean by matter and force; but it is a pleonasm to talk of matter and force as two distinct things; matter is *force and form*, and force can only be spoken of as an abstraction, just as in geometry we speak of a point, a line, a surface, when nothing but solids exist or are possible. But force is higher than form; form being only its ultimate manifestation. Force in a form then is matter, and each apart is nothing; but for the convenience of our thinkings we can mentally separate them.

Of forms it is necessary here to consider the most crude or mechanical only, and of forces those which pertain to them, this being but a slight indicatory sketch of the course to be pursued in any thorough enquiry after the different forms of force or energy, and their convertibility, or whether they can be one converted into another, or merely induced one by another, which is what is called "conservation of force," which expression seems to me just a truism, when one has affirmed that matter is indestructible.

* Swedenborg developed this theory before Boscovich.

† Phil. Mag., 3rd Series, vol. 24, pp. 137, &c.

TELEGRAPH ROUND THE WORLD.

THOUGH the recent able communication of Secretary Seward upon the subject of an inter-continental telegraph via Behring's Straits contains not even a distant allusion to Professor Morse, it must still be gratifying to the venerable electrician to find that the experiment of laying a little line of wire forty miles in length, with a recording machine at the end of it, which he constructed between Washington and Baltimore as long ago as the year 1844, has grown into a vast system, promising so soon to embrace the globe in its operations. For it is a singular fact that, with all the variations in form, the "Morse system," in its essential features, is retained the world over. Then, in regard to submarine lines. Professor Morse's successful experiment in the year 1842, with submerged wires between Castle Garden and Governor's Island (which secured the golden medal of the American Institute), gave the first substantial proof of the practicability of this method of electric communication. It is also proper to observe in this connection that the very next year the project of an Atlantic telegraph was laid down, and its success predicted in a letter to the Secretary of the Treasury, in which Professor Morse said, "Startling as this may now seem, the project will be eventually consummated." Twenty years later, as appears from Mr. Seward's letter just written, energetic minds in England and America have resolved to combine their capital to link the two hemispheres in a single telegraphic circuit.

Two projects are distinctly in mind, besides others less prominent, one looking to a connection westward and the other across the Atlantic; but they can in no sense be considered rivals. As we survey the world at large the telegraphic system represents two sets of meshes, each growing more and more intricate every year, yet completely separated one from the other. The intelligence conveyed by them respectively is vast in amount, and much of it possessing a value which would be enhanced many fold, were there provided a medium for exchange. No single line would be adequate to the demand made upon it, either in Europe or the United States. Mr. Seward's letter examines carefully the merits of the line proposed by P. McD. Collins, who has spent several years in obtaining concessions from Russia and England for the extension of a line via Behring's Straits and Siberia, to connect with the Russian telegraph now completed as far east as Irkoutsk, from St. Petersburg. The extent of the route, we are informed, is not an insurmountable difficulty, as the entire length would be about 6,040 miles, divided as follows:—

In the North-western Territories	1,000	miles.
In British America	600	„
In Russian America	1,900	„
Across Behring's Straits	40	„
To the Amoor River	2,500	„
Total	6,040	„

Lines have been already stretched over steppes in both continents similar to those now proposed. There is no lack of timber. The temperature of the region to be traversed is no more severe than in other remote parts where communication is maintained without difficulty. Indian tribes are so well subject to the restraints of civilization that their resistance is not expected. The expense involved is estimated at $5,000,000, though an association has been formed with a capital of double this amount, and as the co-operation of other Governments is secured already, Mr. Collins only desires that Congress shall grant a right of way across the public lands, with the right to take therefrom materials necessary for constructing the line; the use of a national vessel, suitably officered and equipped, to make surveys and soundings along the North Pacific coast, beyond the limits of the United States, and to aid in prosecuting the work; and finally, a stipulated compensation for the Government use of the line when it shall be constructed.

Of all this Mr. Seward approves.

In regard to the Atlantic telegraph, no doubt is now felt that the work of laying the cable will be seriously undertaken next summer. Glass, Elliot, & Co. are preparing the cable, and it is understood that the Great Eastern has been engaged to aid in putting it down. The French Atlantic scheme is also spoken of as likely to be carried into execution without delay. Of Mr. Shaffner's project, for which concessions were obtained from the King of Denmark, commonly known as the North Atlantic Telegraph, nothing has been heard for some time.—*New York Weekly Journal of Commerce.*

HAWORTH'S PATENT FOR CONVEYING ELECTRIC SIGNALS AND TELEGRAMS.

We publish this week a document which will be read with considerable interest by every one interested in the progress of electro-telegraphy. Mr. Haworth's discovery, of a method of transmitting intelligence between distant places without the aid of conducting wires, has been the subject of discussion for some time. After carefully perusing the lengthy and intricate specification, and the twelve sheets of drawings attached thereto, we confess that the means proposed by Mr. Haworth are incomprehensible to us. We have reproduced two of the drawings, which will, perhaps, to some extent assist our readers in mastering the more unintelligible parts of the specification. It is to be hoped that the inventor will now lose no time in putting his invention to practical test in the presence of competent and credible witnesses. The following is an abstract of Mr. Haworth's specification:—

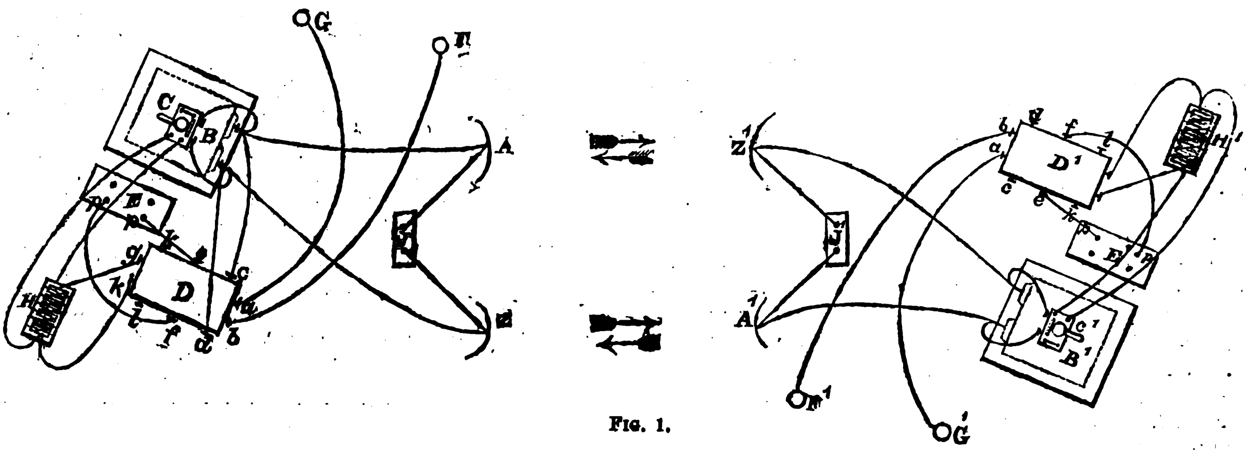

FIG. 1.

In order to effectuate the object in view, the patentee proceeds as follows:—A plate of copper, marked A, and another plate of zinc, marked Z, each separate and distant about three feet from each other, are buried in the earth, but the distance between these plates may be advantageously increased to some extent in proportion to the distance to which the signal is to be sent. They are retained in an upright position and slightly bent, so as to form the segment of a cylinder, the axis of which is perpendicular to the surface of the earth. They are buried in such a position as to present their convex sides towards the place to which it is intended to send signals. For a distance of seventy-five miles and under, it has been found that plates of one foot square are sufficient. For a distance beyond that, and up to 440 miles, plates each 24 inches by 16 inches have been made use of, but the size of the plates may be varied according to distance, or other circumstances. Two cylinders of copper, marked G and F, each two feet long and four inches in diameter, are also buried in an upright position. These cylinders must be buried in the earth at such a depth as will insure their always being surrounded with moisture. They must be separate from each other. Their position is shown in Fig. 1. There are also buried in the earth, behind plates A and Z, at the distance of about three feet from the centre of each plate (the distance may be increased for longer distances, as above mentioned), and in an upright position, a wooden box, marked J, containing a coil of coated copper wire.

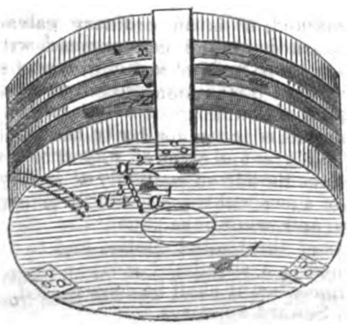

FIG. 2.

The coil which has been found effective is of a flat form, Fig. 2, one inch in thickness, and consists of coated copper wire wound upon a reel, constructed as follows:—Two circular pieces of wood are fixed, of the diameter required, upon a wooden axle, and at right angles thereto. These pieces of wood are kept separate, at an uniform distance, by a circular block or collar of wood of the thickness required; upon this collar is wound the coil in regular successive layers to fill up the reel. The collar used is one inch thick and three inches in diameter; the diameter of the coil in this case is fourteen inches, and for this coil, copper wire, No. 16, insulated, has been used. The reel may be made of wood, well coated with shellac, or other insulating material, or glass. The end of the wire at the centre, and that at the circumference, are connected respectively with the binding screws, shown on box J, Fig. 1.

The binding screws of the box J, are connected with plates A and Z, by means of coated copper wires, to each end of the coil, in an apparatus hereinafter described, and marked B. This apparatus, marked B, consists of a strong wooden box, containing three flat coils, constructed in the following manner:—A reel is made, by fixing four circular pieces of wood, not less than eight inches in diameter, and well coated with shellac, on a wooden axis at right angles thereto, and at equal distances from each other; they are retained in this position by collars or circular blocks of wood placed between them, and also well coated with shellac. These collars correspond with each other in size and thickness. A reel with three compartments is thus obtained, and being of equal depth and width, these compartments correspond to the before-mentioned coils. The first compartment is filled with fine insulated copper wire, wound on the reel evenly and closely together, in regular successive layers, from the centre to the circumference. The end of the wire at the centre, and that at the circumference, are brought to the outside of the reel, and there secured. The next compartment is filled with thicker insulated copper wire, wound in the same direction as in the first coil, and in the same regular manner; the inner end of this wire is brought to the circumference of the coil by a groove up the partition separating coil x from coil y; both ends are secured outside the reel, and connected with the binding screws, as shown in Fig. 2. The compartment, z, is filled half-way up with coated iron wire, wound on

the reel in the same direction as coil *x*, and coil *y*. The ends of the iron wire are brought through the flat side of the reel to the outside of the reel, and there securely fastened. The remaining portion of the compartment, *z*, is then filled to the top with similar coated iron wire, but wound double and in a contrary direction to that in the lower half of the compartment, as indicated by the arrows. These wires are not twisted nor bound together, nor allowed to cross one another, but wound evenly in successive layers side by side. The ends of the coil, both of the single and double iron wire, are securely fastened on the outside of the reel.

The coils found effective for the transmission of signals for a distance of upwards of 400 miles, have been for coil *y*, copper wire, No. 16; for coil *x*, copper wire, No. 32; and for coil *z*, iron wire, No. 20, all coated. The reels on which these coils have for the last-mentioned distance been wound, measure fourteen inches in diameter, of which the collar in the centre occupies three inches; the thickness of the collar being one inch. But the size of the wire, the diameter of the coils, and their thickness, will vary according to distance or other circumstances. The partitions between the coils are three-eighths of an inch thick, and the external sides of the reel one inch and a-half thick.

Both ends of the before-mentioned coil *y*, in box B, are brought into permanent metallic connexion, by binding screws, with the end of the coil surrounding the magnetic needle of a telegraphic indicator, marked C. This indicator is placed over box B, as shown in Fig. 1.

Both ends of the coil *y*, in box B, are connected by wires with the binding screws *c* and *d*, in the apparatus hereinafter described, and marked D. The apparatus marked D (which is called the condenser) is contained in a wooden box, of sufficient dimensions to contain the plates and other material connected therewith, hereinafter mentioned. The box is divided lengthwise, by a partition, into two compartments; the interior is well coated with shellac. In each compartment a band of stout gold foil, well insulated, is placed. The band is securely attached at each end to the binding screws at the extremities of the compartments, that is to say, as to one compartment to the binding screws, *a* and *g*, and to the other compartment to the binding screws, *b* and *h*. Each compartment is filled with rectangular plates of gutta-percha, on which insulated copper wire is carefully wound. The wire on these plates of gutta-percha is passed from one plate to another in succession, so as to form one continuous communication throughout each compartment, and the extreme ends are attached to binding screws, *a*, *g*, *b*, and *h*, respectively. The binding screws, *c*, *d*, *e*, *f*, *k*, and *l*, are fixed in the positions shown in Fig. 1, connected with the wire upon the plates in its passage through the box, marked D, and then passed from end to end of each compartment over the gutta-percha plates, and lying upon them, but well insulated from them, another band of stout gold foil, similar to that described above, and each end of it connected with the above-named binding screws, *a*, *g*, *b*, and *h*. The condenser or apparatus marked D, used contains sixty plates of gutta-percha in each compartment, each plate being three inches by four and a-half inches, and nearly one quarter of an inch in thickness. The wire used is coated copper wire, No. 32, the gold foil is three and a-half inches broad, and No. 34 in the wire guage as to substance. For a coil of the dimensions of that hereinbefore described as contained in box, marked B, it is found that the apparatus, marked D, as hereinbefore described, will suffice. For a coil of lesser dimensions than that hereinbefore described in box, marked B, say one of eight inches in diameter, only twenty-five plates of gutta-percha are required in each compartment, and the gold foil one inch and three-eighths broad, only of a similar substance.

The binding screws, *e* and *f*, in the condenser or apparatus, marked D, are connected with binding screws, *p* and *p*, in an apparatus next hereinafter described, and marked E. The apparatus, marked E, contains two coils of copper wire wound upon a reel constructed with two compartments only, but in all other respects constructed in a manner similar to that described in reference to coils *x* and *y*, in the apparatus contained in box B. Each of the coils in apparatus, marked E, is constructed with two copper wires, the one insulated, and the other not insulated, wound alternately side by side evenly in successive layers, from the axis to the circumference. The coil in box E is formed of coated copper wire, No. 21, and copper wire not coated, No. 18. It is desirable that the coating of the copper wire, No. 21, should be of such a thickness that when wound the two wires may present as even a surface as possible. The other coil is formed of coated copper wire, No. 30, and copper wire not coated, No. 24; the inner and outer ends of the coated wire in the first coil are respectively connected with the binding screws, marked respectively *p* and *p*, and the ends of the coated wire in the above second coil are securely fastened on the outside of the reel. The ends of the uncoated wire in each coil are securely fastened on the outside of the reel in such a position that they can never come in contact with any uncovered part of the coated wire. Between each of the layers of wire is placed a strip of non-metallic paper, the width of the compartment, to insulate it from the layer above and the layer below, and when in winding within an inch of the circumference of the reel, gutta-percha tissue is employed, in addition to the non-metallic paper.

The binding screw, marked *g*, in the condenser or apparatus, marked D, is connected to one of the poles of a galvanic battery, marked H; and the binding screw, marked *h*, in the condenser or apparatus, marked D, with the opposite pole of the same battery. The battery used is Smee's battery, regulated according to the strength required.

The same poles of battery H are connected with the binding screws of an ordinary telegraphic indicator, marked C, so as to be capable of being brought into connection with its coil by the motion of the handle. It is suggested that all the wood used in the several apparatus before described be of well-seasoned wood, and, as a general rule, coated.

At the point to which it is intended to transmit the message or telegram is a set of apparatus similar in all respects with that hereinbefore described in Fig. 1, and in the earth is buried a zinc plate, marked Z¹, and a copper plate, marked A¹, similarly curved, and similar in size and position, and for similar uses as copper plate A, and zinc plate Z, hereinbefore described. The plates, Z¹ and A¹, should be buried opposite to, and with their convex sides towards, plates A and Z. The zinc plate Z¹ being buried opposite to the copper plate marked A, and the copper plate A¹ being buried opposite to zinc plate Z; a box marked J¹ is buried in the ground, containing an apparatus similar in all respects to the apparatus hereinbefore described, and contained in the box marked J. Box J¹ is placed at a distance, and in a position relatively to plates Z¹ and A¹, similar to that of box J, with plates A and Z.

Two cylinders are also buried in the ground, marked respectively G¹ and F¹; the cylinders marked G¹ and F¹ are of copper. These cylinders respectively are of the same dimensions, and are placed in the same position relatively to each other as the cylinders G and F hereinbefore described, and are connected with the apparatus contained in the box D¹, hereinafter mentioned, in the same way as the cylinders, respectively marked G and F, are connected with the apparatus in box D, hereinbefore described.

The apparatus contained in the box marked D¹ is similar in all respects to that hereinbefore described and marked D.

The apparatus contained in the box marked D¹ is connected with the respective apparatus, marked respectively B¹, E¹, H¹, and C¹, by a method similar to that in which the apparatus marked D is connected with the respective apparatus respectively marked B, E, H, and C.

The apparatus contained in the box marked B¹ is similar in all respects to the apparatus contained in the box marked B, and is connected with the respective apparatus marked D¹, E¹, and C¹, and with the plates A¹ and Z¹, in a way similar to that by which the apparatus marked B is connected with the respective apparatus marked respectively D, E, and C, and with the plates A and Z.

The apparatus contained in the box marked E¹ is similar in all respects to the apparatus contained in the box marked E, and is connected with the apparatus marked D¹ in a way similar to that by which the apparatus marked E is connected with the apparatus marked D.

The battery marked H¹ is an ordinary galvanic battery, and similar to that marked H, and is connected with the respective apparatus marked respectively D¹ and C¹ in a way similar to that by which the battery marked H is connected with the apparatus marked respectively D and C.

The apparatus marked C¹ is similar to the telegraphic indicator hereinbefore referred to and marked C, and is connected with the respective apparatus marked respectively B¹ and H¹ in a way similar to that by which the indicator marked C is connected with the respective apparatus marked B and H.

ADVANCEMENT.—In science there is work for all hands; and he is usually the most fit to occupy the highest post who has risen from the ranks.

THE INTER-CONTINENTAL TELEGRAPH.

As several paragraphs relating to the above great undertaking have appeared in our columns, we are now, through the courtesy of an esteemed friend, enabled to place before our readers the letters which have passed between Mr. Chandler and Mr. Secretary Seward on the subject :—

MR. CHANDLER TO MR. SEWARD.

Senate Chamber, Washington, April 14, 1864.

Hon. William H. Seward, Secretary of State.

Sir,—I have the honour to transmit herewith a printed copy of the memorial of Perry McD. Collins, representing that he has obtained from the Government of Russia a grant of the privilege to construct a telegraph from the mouth of the Amoor River to the Russian possessions in America, and a similar grant from the British Government in British Columbia, and praying the co-operation of the Government of the United States to enable him to complete his enterprise.

The Committee on Commerce of the United States Senate, to whom this memorial has been referred, will be glad to receive from you such information upon the subject as may be in the possession of the Department, together with your views upon the expediency of granting the prayer of the memorialist.—I have the honour to be, Sir, your obedient servant,

Z. CHANDLER,
Chairman of Committee on Commerce of the United States Senate.

MEMORIAL OF MR. COLLINS.

To the Honourable the Senate and House of Representatives of the United States of America in Congress Assembled:

The memorial of P. McD. Collins, a citizen of the United States of America, and a resident of the State of California, most respectfully represents: That he has obtained from the Imperial Government of Russia privilege to construct a line of telegraph from the mouth of the Amoor River, in Asiatic Russia, to the frontiers of the Russian possessions in America, adjoining the possessions of Great Britain.

In connection with the grant from Russia, the Russian Government stipulate, upon certain conditions, to construct a continuous line of telegraph connecting the European system with the Pacific Ocean, about 8,500 miles east of London, and on the route of a line which may be projected to Pekin and the great commercial cities of China.

Your memorialist also represents that, after having obtained the Russian grant, and upon a representation of the state of the case and the facts to the Government of her Majesty, that he has been authorised by the British Government to construct a line of telegraph across the intervening territory of British Columbia. Thus the grants from Russia and England authorise the construction of a continuous line of telegraph, which is to connect Europe with the United States, across the whole of Asia, and the northwest coast of the Pacific.

The whole country, except a portion of the route in British Columbia, over which this proposed line must pass, is sparely inhabited, and presents no local inducement for the construction of a telegraph.

The sole inducement to the construction of a telegraph over this great extent of country is the union of Asia and Europe with the American system of telegraph lines, and by as nearly as physically possible an overland route.

The great progress of telegraphs both in Asia and America since the proposition was originally made to induce a trial of this northern overland route, in order to unite Europe and America, has cleared away from the path of this enterprise many apparent difficulties suggested in the early stages of the undertaking.

Russia has extended her telegraph from St. Petersburg to Irkoutsk, a distance of 4,000 miles to the east; and now a line is being constructed along the Amoor River, which is to connect with the line in course of construction from Irkoutsk to the east. Thus it will be seen that Russia is rapidly approaching with a continuous line the Pacific Ocean.

On our side of the world we have already reached the Pacific, and up towards the British possessions, and as far as Portland, Oregon.

From our northern frontier, adjoining British Columbia, to the mouth of the Amoor River, in Asiatic Russia, the distance may be stated in round numbers at some 5,000 miles.

Previous to granting right of way for the construction of a telegraph, the Russian Government authorised your petitioner to survey a route over all that portion of the Russian dominions east of the Amoor on to British Columbia.

On two previous occasions your petitioner presented to Congress the facts of the case, and reports were made thereon, copies of which are herewith annexed, marked A and B.

The reasons which then existed not only hold good now, but are greatly enhanced by the absolute grant of right of way then withheld.

There is much in the North Pacific valuable to us as a nation in a commercial point of view, aside from the special interest particularly involved.

Our Pacific whaling fleet resort in considerable force to the seas, bays, and sounds, not only of the Pacific, but of the Arctic; in one year more than 70 American vessels have passed through Behring's Straits, and largely over 100 have visited the waters adjacent and the Otchotsk Sea.

The commerce of Japan and of the Amoor region increasing from year to year, makes it requisite that we should have a more perfect knowledge of these interesting regions of the North Pacific.

In view of the premises, and furtherance of American commerce and enterprise, and the vast and incalculable benefits to result to us, as a great commercial nation, out of the achievement of telegraphic communication which shall not only unite Europe to America, but add the whole of Asia, including Japan, China, and India, your petitioner most respectfully asks the favourable consideration of Congress, and that aid for a survey of the proposed telegraph, and a subsidy, in the form of a contract for the despatch of Government messages, be accorded, so as to meet the concessions of Russia and Great Britain in a co-operative, international spirit, and for general intelligence of all nations. And, as in duty bound, your petitioner will ever pray.

PERRY McD. COLLINS.

SECRETARY SEWARD TO HON. Z. CHANDLER.

Department of State, Washington, May 14, 1864.

To the Hon. Zachary Chandler, Chairman of the Committee on Commerce in the Senate of the United States:

Sir,—I have the honour to reply to your letter of the 14th of April last upon the subject of the memorial which has been submitted to Congress by Mr. Perry McDonough Collins.

Mr. Collins is an American citizen, residing in California. He has been, since 1856, commercial agent of this Government for the Amoor River. The public archives, as well as the records of Congress, furnish satisfactory evidence that the country could not have a more enlightened, assiduous, and faithful representative.

The project which he submits for the consideration of Congress is the construction of a line of telegraph from some point on the Pacific telegraph line, or the northern extension thereof in one of the north-western States or territories, across the border of the United States, and through British Columbia and Russian America to Cape Prince of Wales, thence by an inland route around the Sea of Ochotsk to the mouth of the Amoor River.

The telegraph line thus proposed is intended primarily to connect at the last-named place with a line to be extended from thence to Irkoutsk, the capital of Eastern Siberia.

At that important town a line of telegraph begins, which stretches through Yomsk and Orusk, in Western Siberia, Katherinburg on the Asiatic European frontier, Perin, Kasan, Nijni-Novgorod, and Moscow to St Petersburg, the capital of the Russian empire.

The line projected by Mr. Collins, from the Pacific Telegraph to Amoor River, with its anticipated extension by the Russian Government to Irkoutsk, would be the one link now wanted to supply direct and unbroken telegraph communication from Cape Race in Newfoundland, on the eastern coast of America, across the eastern and western continents and the Pacific Ocean to Cape Clear, in Ireland, the westernmost projection of Europe.

When a submarine telegraph shall be successfully laid between Cape Clear and Cape Race it will, together with the link I have last before described, complete a telegraphic circuit around the earth between the parallel of 42° and 65° of north latitude.

Three questions arise from Mr. Collins's memorial, namely :—1st. Is the enterprise feasible? 2nd. Would it be useful? 3rd. Has it a just claim on the Government to the patronage which he solicits?

The secretary then proceeds to discuss the three questions of the feasibility of the proposed route. He esteems the mere extent of the route to be traversed not insurmountable nor even a serious difficulty, the climate favourable, and if Congress shall grant the application, Great Britain and Russia, having already acquiesced, will not interfere. He leaves the expense of the enterprise to the estimate made by Mr. Collins in his memorial. He then says :—I proceed, in the next place, to consider the probable usefulness of the enterprise. It is needful here to assume that the line of telegraph proposed will be extended immediately from Amoor River to Irkoutsk, so as to complete the telegraphic chain over the two continents. The agreement of Russia leaves no room for doubt on this point.

It is quite too late at this day to debate the abstract question of the usefulness of the magnetic telegraph. It would be as easy now to dispense with the steam-engine on land or on sea, in the business of commerce, in social intercourse, or in political affairs, as it would be to forego the use of the telegraph. To be without it is to be isolated. Other conditions being equal, the country that has the largest extension and the most thorough radiation of the telegraph wire enjoys the most active and profitable system of domestic commerce.

Of the 80,000 miles of telegraph now in operation on the American continent, 60,000 miles are found within the United States, and the remainder in the provinces of British America. But commerce on the American continent defies political restraint, and centralizes itself within our own country. For practical purposes we may regard the whole telegraph system of the American continent as our own. But internal commerce imparts life to, and receives new life in return from, foreign commerce. In proportion to the extent and variety of its resources, the nation that enjoys the most prosperous foreign commerce exhibits the greatest industrial activity and domestic happiness within its own borders.

The vigour which commerce has already attained among us, while we continue to hold our communications with the eastern continent by navigation only, is justly a subject of national congratulation. Can there be a doubt that if our telegraph system should be connected by transoceanic line with the one that is now performing its equally isolated part on the eastern continent, new and stronger reciprocity would be exhibited not only in commercial centres, but in every recess of the land? The unremitting exertions which are made by enlightened men in Europe and the United States to connect the two countries by a wire passing through the Atlantic Ocean, as well as the responses which Great Britain and Russia have made to the application for favour and patronage to the line now under consideration, show the existence of a very wide and general conviction that each of the isolated telegraph systems existing on the two continents is imperfect and incomplete, and relatively inefficient, and that a connection between them is a necessary supplement to secure their greatest attainable usefulness.

The secretary proceeds to consider the question whether the enterprise deserves the patronage Mr. Collins solicits for it. Throughout the remarks which I have thus far submitted, I have not, without design, called it Mr. Collins's enterprise. It is truly his, because it was he alone who conceived and projected it, and who has clothed it with the substantial form which enables the great States, whose concerted action he solicits, to cause it to be put in operation. But in another sense it is entitled to be regarded as an enterprise of the Government of the United States. During all the time that Mr. Collins has been engaged in maturing and developing it, and presenting it to the consideration of Russia and Great Britain, he has been acting under the instruction and with the approbation of the Department of State, and a knowledge of that fact has not been withheld from Congress.

I think it may be regarded as settled that the United States cannot neglect to employ telegraphic communication with foreign countries, and yet expect to maintain a healthful commerce with them; that the United States cannot hope to inspire respect, confidence, and good-will abroad, and so secure peace with foreign States, without using the magnetic telegraph when it is possible; and that the United States cannot even hope to preserve peace and order at home, much less to maintain a military and naval police on their inland frontiers and around their ocean posts, without availing themselves of all feasible telegraphic communications.

Finally, it seems to me that in extending dominion over inland mountain regions, and setting up the national flag on the Pacific coast, the American people, however inconsiderately, assumed the duty of diffusing an equal civilization throughout the whole of the great country which they thus included within their borders. Nor would it be wise to shut out from our thoughts the consideration which necessarily results from contemplating calmly the positions and the resources of new north-western and western States. It becomes our duty to act upon the conviction that, from this time henceforth, those States are to perform an important part in a great work which shall make the shores of the Pacific Ocean the home of communities that shall be as busy, as prosperous, as free, as enlightened, as powerful, and as happy as those which now cluster upon the Atlantic shores. The Atlantic States, by their intermarriage with those of the Pacific, have come under an obligation to favour this great development.

What Mr. Collins asks of Congress is the grant of a right of way across the public lands, with the right to take therefrom materials necessary for constructing the line; the use of a national vessel, suitably officered and equipped, to make surveys and soundings along the North Pacific coast, beyond the limits of the United States, and to aid in prosecuting the work; and finally, a stipulated compensation for the Government use of the line, when it shall be constructed. If the views I have submitted are just, this demand for patronage is neither unnecessary nor unreasonable. We could not withhold it without showing a want of appreciation of the liberality and friendship which have been manifested towards the United States by Russia and Great Britain in the proceedings they have adopted towards the same enterprise. I do not know any one object lying within the scope of our foreign relations more directly important than the preservation of peace and friendship with these two great and enlightened Powers. Nor can I conceive of any one measure of national policy that would more effectively tend to secure that great object than the construction of the proposed intercontinental telegraph.

I forbear to urge the project in competition with the proposed line across the Atlantic from Cape Clear to Cape Race, which, notwithstanding past difficulties, I yet hope to see speedily completed. The two lines would naturally aid and strengthen each other. If they should even come into competition, it would be more advantageous to the world to have the use of both than the use of only one of them. One might be expected to operate when the other should be accidentally suspended. Nor can it be reasonably doubted that the great interests of human society will, at a very early period, require more than one, and more than even two, transoceanic, world-encircling telegraphs.—I have the honour to be, Sir, your obedient servant,

WILLIAM H. SEWARD.

METEOROLOGICAL PHENOMENON.—Towards the end of last month an electric cloud passed over Keith and Fife-Keith, in Scotland, occasioning a deposit of sulphurous matter on the surface of exposed water in the district as thick as a sixpence. The pools on the wayside were similarly affected.

THE PERSIAN GULF TELEGRAPH.

(*Continued from page 6.*)

To admit of more accurate reductions of the tests made in different temperatures to those made at the given temperature (24° centigrade), a series of experiments were instituted by Messrs. Bright and Clark, and carried out, to ascertain the resistance of the two materials at every 2° of centigrade between 0 and 38. The average resistance of the conductor at 24° centigrade was about 6·53 Siemens' units per nauticle mile, while the gutta-percha offers a resistance of 220 millions of units per nautical mile. This must not be confounded with the specific resistance of the two materials; the first is the total resistance of a piece of copper a mile long, and having a sectional area equal to the section of the conductor; the second is the resistance of a hollow cylinder of gutta-percha in the direction of its radius.

Its sectional area is approximately equal to the mean between the inner and outer circumference multiplied by one nautical mile, and the length of this conductor is the thickness of the gutta-percha covering.

The quantity of electricity passing through the conductor and insulator would be respectively inversely as these figures, or, in fact, on a length of one mile the quantity of electricity passing along the conductor would be 3,384,615 times greater than that lost by the conduction to the sea through the gutta-percha covering, and supposing a length of 300 miles, by a simple calculation we find that the quantity of electricity passing to the distant station would be 376 times greater than the quantity lost through the insulator on the whole 300 miles.

It was found that the resistance of the gutta-percha increased, when tested under pressure, about 16 per cent. per 600 lb. pressure. It also increased considerably with age: thus a coil which had, when tested on the 17th March, a resistance of 238 millions, had, when tested on October 23, 370 millions of resistance. The improvement with age augurs well for submarine telegraphy, and has been fully corroborated by the tests of the cable in the Persian Gulf. The joints in the core were all tested separately by a system devised by Mr. L. Clark, which admits of far greater accuracy in the detection of the minute leakage which occurs when a joint is imperfectly made than any system hitherto adopted. This system was fully described by Professor Thomson last May at the Royal Institution.

The core when tested was carefully wound on large drums in lengths of three to four miles, and delivered to Mr. Henley, at his factory at North Woolwich, to whom the contract for the completion of the manufacture of the cable was entrusted by the Government of India. The design of the protecting parts differs to some extent from that of other cables, and consists of, first, a serving of soft yarn wound round the core, which again is surrounded by twelve galvanized iron wires of No. 7, Birmingham gauge, of 0·18 of an inch diameter. As has been already pointed out, such a cable, though far more protected than the Red Sea or Mediterranean cables, by reason of the increased quantity of iron and the galvanizing of the latter, would still be liable to perish from rust at places after some time. As a further precaution, therefore, the following coating, designed by Messrs. Bright and Clark, was placed round the iron wires:—First, a serving of the best Russian hemp yarn is wound round the iron cable, and is then covered with a thick layer of mineral pitch, mixed with silica and applied warm. This is again covered with a second serving of hemp in the reverse direction to the first, and in its turn is again covered with another coating of warm compound, the whole finally passing through grooved rollers, so as to consolidate the whole and to produce a smooth and cylindrical surface. Thus the iron wire is effectually protected from contact with the water by a solid cylinder of hard asphalte, bound together by innumerable fibres, acting, as it were, as bond courses. This process has been already adopted in a less perfect manner on cables in the North Sea and Irish Channels, when only one serving and coating, however, was used, and has been found an excellent protection against rust.

The machines for applying this coating consist of two tanks, the one behind the other, and heated by steam jackets. In front of each of these is a disc carrying bobbins, on each of which is wound a length of hemp yarn. The cable passes through mandrils, on which the discs are attached, and over (not through) the compound in the tanks, the compound being lifted and poured on to the cable, as it passes along, by means of a small wheel with internal paddles; any superfluous compound that adheres to the cable being removed by a movable dish.

These machines, of which there were six, together with an iron shed over all the cable tanks, as required by the specification, and various fittings and preparations for testing, had to be designed and erected especially for this work.

Owing to the engineering knowledge possessed by Mr. Henley (a knowledge rather scarce amongst submarine telegraph contractors) and his readiness to oblige and meet the views of the engineers (a quality still more scarce among submarine telegraph contractors), many little difficulties in the adaptation of the necessary machinery were speedily overcome; and, indeed, when we consider that the contract was only let in December, it reflects the highest credit on Mr. Henley and his engineer, Mr. Frasi, when it is stated that the cable was fully started in February. The cable, as manufactured, was coiled into tanks and kept submerged in water; tests were taken of the core both on the arrival at Woolwich from the Gutta-percha Works, and every day on each section under manufacture by

a staff of electricians, under Mr. F. C. Webb, who superintended the manufacture of the cable on the part of Messrs. Bright and Clark, as also the shipping of the cable, the designing of the machinery, and fitting of the ships.

To ensure a perfect test of the core of insulation, the hemp serving between the core and the iron wire consisted of white Russian washed in salt water (a system patented by Mr. Willoughby Smith), as it has been found in practice that when the hemp is tarred a faulty place may be stopped up by the tar, and thus the cable will test, until the tar is dissolved, which sometimes does not occur until the cable has been submerged for some weeks or months.

The shipping and laying the Persian cable presented also some points of novelty and interest.

Most cables have been laid from steamers, and in the few instances in which sailing vessels under tow have been employed, the result has been (except in one instance, viz., the Dover and Calais cable) * the loss of the cable.

Thus one of the cables from Cagliari towards Bonah was lost, and another across the Gulf of St. Lawrence. To have taken a cable of the length of the Persian Cable, weighing about 5,000 tons, round the Cape in steamers would have been a considerable expense as compared to the cost of the whole work. Besides which it would have been very difficult to obtain sufficient steamers of the necessary construction for taking large coils without considerable delay. The idea of sailing vessels under tow was, therefore, once more discussed. It was shown on good authority that the prospect of fine weather in the Persian Gulf during the months of spring was considerable, and as the route of the cable lay in shoal water, where it could easily be grappled if any mishap should take place, it was determined by Colonel Stewart to try once more this more economical mode of laying a cable. And it is only due to Colonel Stewart to observe that in deciding this question he was opposed by most of the engineers; and, indeed, certain contractors and their engineers laughed at the idea. At the same time it is obvious that as a sailing vessel under tow cannot be stopped so easily or quickly when required as a steamer, this mode of laying a cable imposes a more arduous task upon the engineers actually employed in the operation of laying, and by whom, in in this instance, every precaution was therefore taken to avoid, as much as possible, the occurrence of any hitch in paying out.

There remained, however, still the difficulty of the change from hold to hold, and in which case the calculation of the time the ship will lose her way requires, accordingly, the greatest nicety of judgment.

The Marian Moore, of 1,036 tons, Captain Munce; the Kirkham, 1,061 tons, Captain Routledge; the Tweed (late the Punjaub), 1,744 tons, Captain Stuart; the Assaye, 1,528 tons, Captain Thomas; and the Cospatrick, 1,199 tons, Captain Elmslie, were taken up by Government. In addition to these ships, the Government purchased a small screw steamer of 441 tons, called the Charente, and re-named her the Amber Witch. This vessel was fitted with three water-tight tanks, for receiving cable, a break, and a complete machine for picking up (*i.e.*, winding in) cable by steam, and, indeed, with all other machinery for grappling, buoying, under-running, picking up, and laying cable. She is to be stationed in the Gulf as a general means of relieving the staff and provisioning the stations, as well as for repairing the cable should it break down at any time.

She is commanded by Lieutenant Stiffe, late of the Indian Navy, an officer of much experience in surveying duties in the Gulf, and who, in addition to his experience as a naval surveying officer, has served his time in a civil engineer's office in London. Captain Stiffe, besides commanding the Amber Witch, will hold the office of engineer to the line; and there is little doubt that a better officer for the work could not have been selected.

These five large vessels were fitted each with three water-tight cylinders, or tanks, to receive the cable. These cylinders, which were mostly elliptical on plan, varied in dimensions from 23 feet by 26 feet in diameter, by 10·3 feet deep (viz., the fore tank of the Marian Moore) to 32 feet by 34 feet diameter, by 15 feet deep (viz., the main tanks of the Assaye and Tweed).

In the centre of the tanks a solid wood centreing was fixed in the shape of the frustrum of a cone, and having a perfectly smooth surface, rounded off at the top edge to a radius of 1 foot. Round this cone, and near the top a ring was fixed, leaving a clear space entirely round the cone, and between it and the ring. A second ring, of larger dimensions, and in some cases a third, is fitted with machinery, so as to lower down, and yet remain rigid in any place to which it is lowered as the cable is payed out.

Between these rings and the cone the moving part of the cable passes, and sweeps regularly round, being guided in its course by the cone on the interior, and the rings on the exterior, of its path. Above the centre of the cone is fixed a bell-mouthed casting, through which the cable passes. This was so contrived that, by the removal of a single pin, it could be opened to free the cable when changing from hold to hold.

The rings were also fitted with loops or bays, in which the bottom part of the cable leading to the next hold was placed. The rings being made complete by means of a solid piece, secured by two pins, are easily removed by a hammer.

From the cast iron hawse the cable passes over a cast iron saddle or quadrant, fitted with rollers in some cases, and thence it changes to a horizontal direction along a series of fair leaders, having rollers in them fixed on a long platform erected in a fore-and-aft direction along the ship. This platform is placed at such a height, and at such a gradient, as to lead the cable with the least bends possible to the machinery for paying out. The system of cones and rings is claimed as a patent by Mr. Newall, and the Government pay a royalty for its use. The particular proportions of the cones, and the mode of arranging the fixed and moving rings, and the arrangements for maintaining the latter firm, together with some improvement in the latter which prevents the necessity of taking out a whole segment of the ring when changing from hold to hold, were designed by Mr. F. C. Webb, when fitting the ships. The break consisted of a cast-iron drum, 6 feet in diameter, and having a break similar to a crane break on one side, fixed on a 7-inch shaft, 6 feet long, supported on two bearings on the same side. On this shaft a second break wheel was fixed 5 feet in diameter. The cable made four turns round the break drum, and then passed over a 4-feet sheave fixed over the stern of the ship. The 5-feet break was used in general, the larger break being only used as a precaution if it should be found necessary to restrain the cable at all costs to save life or limb.

The cable was coiled on board the ships as they arrived in succession opposite the factory at Woolwich, under the superintendence of Sir C. Bright and Mr. F. C. Webb; Mr. Henley also undertook this part of the work by contract. As the cable was coiled on board, the tanks were filled with water, and, when filled with cable, decked over. One of Gwynne's centrifugal pumps, worked by a small steam-engine, was fitted to each ship, for pumping the tanks up should they at any time require pumping out or filling. Each ship was fitted with proper instruments and batteries for testing the cable in a cabin fitted up especially for the purpose, under the superintendence of Mr. J. C. Laws, and the cable was tested regularly every day during the passage out by one of Messrs. Bright and Clark's staff, sent in charge of the cable; Mr. Wood being in charge of the cable in the Assaye, Mr. Moseley in the Tweed, Mr. Walker in the Kirkham, Mr. Donovan in the Marian Moore, and Mr. Crookes in the Cospatrick.

The ships left Woolwich, or Victoria Docks, on the following dates:— Marian Moore, August 15th; Kirkham, September 11th; Assaye, September 23rd; Amber Witch, October 21st; Tweed, October 24th. The Assaye, which put into Plymouth with her mainmast sprung during a gale, was detained to have a new mast fitted, and sailed finally October 14. The Tweed also put into Torbay through stress of weather, and sailed finally November 6th. The vessels arrived at Bombay in the following order:— Marian Moore, December 22nd, 1863; Kirkham, January 13th, 1864; Tweed, February 6th, 1864; Assaye, February 12th, 1864; Amber Witch, March 2nd, 1864; Cospatrick, April 16th, 1864. As soon as the Marian Moore and Kirkham had arrived at Bombay their machinery, which had been stowed for the voyage, was again fixed, and every arrangement made for paying out, under the superintendence of Sir Charles Bright, who had arrived with his staff at Bombay on the 10th of December; the electrical arrangements being in the charge of Mr. J. C. Laws, and the arrangements for paying out under Mr. F. C. Webb,—the general arrangement for the departure of the ships being made by Colonel Stewart and Captain Young, C.B., the captain superintendent of her Majesty's dockyard.

On January 21st, the Coromandel, Captain Carew, having on board Colonel Stewart, Captain Stewart, Sir C. Bright, and Dr. Esselbach, left Bombay, and in the evening of the same date was followed by the Kirkham, in tow of the Zenobia, Captain Carpendale, and the Marian Moore, in tow of the Semiramis, Captain Crocket.

(To be continued.)

THE NEW GUM, BALATA.—At a meeting of the Society of Arts, held at Willis's Rooms, on the 24th ult., His Royal Highness the Prince of Wales presented the silver medals of the Society awarded to Dr. Van Holst, of Berbice, for the importation into this country, through Mr. Walker (Colonial Secretary of British Guiana), of specimens of balata, a gum from the *Sapota Mulleri*, as a substitute for gutta-percha; and to Sir William Holmes (of British Guiana), for the introduction of this material into the commerce of the country. Mr. M. H. Marsh, M.P., in adverting to the awards, said "They were all aware of the great commercial value of gutta-percha. It was a material which had been introduced only within the last few years, and it was now of the most extensive application. It was used for objects of great variety of character, from the half-penny toy of the child to the great electric telegraph which could waft a sigh from India to the Pole, defying space and time, and which was one of the greatest discoveries of the age, when mind triumphed over matter in a way that no previous age had witnessed. Gutta-percha was a natural production; its sources of supply were limited; the trees from which it was derived were continually cut down, and the supply must ultimately fail, and hence the importance of discovering some efficient substitute. The eminent colonists to whom the society's medal was awarded had been fortunate, the one in discovering, and the other in introducing into commerce a gum of another kind which could be used as a substitute for gutta-percha, and he was sure the meeting would agree that they were immensely entitled to the distinction which was now conferred upon them."

* In this instance also the towing hawser broke, and the ship containing the cable drifted so much that the cable ran short, and was not completed until some weeks afterwards.

THE AMERICAN COMMISSIONER ON THE POLICY OF PATENTS.

(Concluded from page 9.)

(Concluded from page 9.)

I proceed next to a review of the progress of the arts in this country within the last one or two years, as exhibited in the different classes of inventions which have been the subjects of examination during this period. For minute information reference must be had to the carefully prepared brief descriptions of all the patented inventions, with the claims of each patent for the present year, and the admirably executed plates of drawings which accompany this report.

I am withheld, for obvious reasons, from giving the names of particular inventors, even when they may have exhibited extraordinary merit, and shall attempt only such a general sketch as may indicate the direction which the industry of the country has taken, and may be suggestive to ingenious minds of the fields of invention in which there is the most promise of reward for exploration and discovery.

Upon assuming the head of this office, I found the classification of inventions, by means of which the work of examination was distributed into distinct departments, and the vast collections of drawings and models arranged for ready reference, defective in philosophical arrangement, while the development of new branches of industry exhibited the need of forming new classes; I therefore prepared a new classification of the subjects of invention, which was published for the guidance of the office, and for facilitating inventors and agents in their reference to drawings and models.

The alphabetical classification extends over many pages, embracing a consideration of nearly every process in the arts and manufactures; but as our readers are more particularly interested in telegraphy, we pass over the subjects until we come to class N, which treats on mathematical and philosophical instruments, electricity, &c., where the American Commissioner says:—

In almost every subdivision of this class inventive genius has been successfully active; and although the subjects are apparently among the most peaceful pursuits of life, yet the present war has elicited some valuable contributions to the progress of improvement in this connection. Among the patents intended more particularly for army and navy purposes are telegraphs for the field and for use on shipboard, for steering purposes, and communication with the engineers; electric fuzes for cannon and blasting, torpedoes, signals on land and at sea, telescopes for rifles, telescopes for measuring distances, field glasses, mariners' compasses for iron-clad vessels, and others of indirect relation, such as portable scales for weighing and engineering apparatus, designed especially for army and navy uses.

These have all passed in review and received the sanction of letters patent. Conspicuous among them is a magneto-electric telegraph, now in extensive use in the United States army for field purposes, and elsewhere for ordinary telegraphic purposes. This is a signal triumph in electro-mechanics, for by the motive power of a small magneto-electric machine, occupying less than a cubic foot, a dial or index telegraph is operated through great distances, from five to two hundred miles, with the prospect of greater and indefinite extension. It was found with the Atlantic telegraph in 1858, that alternating or to-and-fro currents were indispensable to its operation, and the magneto-electric machine of the telegraph before us has the peculiar movement of normal to-and-fro currents in rapid succession, without any extra contrivance for their production, this condition growing out of the very arrangement of the magnetic poles and helices. The operators for this telegraph require no training, and any person who can read can telegraph. For the Morse telegraph two or three years of training are required. It is not liable to piracy by tapping, as is the Morse telegraph, and may be justly regarded as the inauguration of a new era in telegraphy, by dispensing with the cumbersome, uncleanly, unhealthy, and inconstant galvanic battery as the motive power, and the introduction of a simple and economical telegraph, adapted with equal facility to domestic and public purposes. It is not too much to say that the days of telegraphing by the galvanic battery are numbered, and that the magneto-electric machine will ere long take its place for this as well as for many other purposes.

Another highly interesting development in magneto-electric science is the discovery and application of a new mode of ignition for purposes of blasting with powder. Hitherto torpedoes and other powder blasts, fired by electricity, have depended upon the ignition of a very fine platinum wire. When this had to be done through long circuits or at great distances, very large and expensive galvanic batteries were required, owing to the great diminution of the quantity of electricity. It was proved by experiments made at the Capitol many years since that 150 pairs of Grove's battery were necessary to ignite powder by the finest of platinum wires placed in the telegraphic circuit between Baltimore and Washington, a distance of forty miles. By means of this new discovery powder has been fired through the distance of 100 miles by means of a little magneto-electric machine, occupying less than a cubic foot. This astonishing achievement has been accomplished by means so simple that electricians will wonder as much, if not more, than the uninitiated. It is done by a *pencil-mark*. The stroke of a common blacklead pencil on a block of wood is substituted for the platinum wire, and this disintegrated conductor, as it may be called, is so intensely ignited by the magneto-electric current as to set fire to the wood.

The application of this ingenious device within a suitably prepared cartridge will be hailed as one of the most valuable contributions to mining and engineering operations of the present day.

Following upon this discovery was an interesting application to the firing of cannon by magneto-electricity, dispensing with the vent or touch-hole, which, although hitherto a necessity, has been regarded as a weak point in cannon.

Experiments made at the navy yard in this city prove the firing by this method to be wholly successful, one thousand cartridges having been fired by the inventor without a single failure.

A patent has been granted for an electro-magnetic telegraph for steering vessels, and public exhibitions made of the practical operation of the system. By very ingenious mechanism, the orders of the pilot to the engineers and helmsmen are given with such promptness and unmistakeable precision, that its early introduction, especially in the immense vessels of the present day, may be reasonably looked for.

The electric and magneto-electric lights have also been subjects of examination and of patents, and there can be no material doubt now as to the practicability of the magneto-electric light for lighthouses and other purposes of signal lights.

The magneto-electric current passing between charcoal points has been used in a lighthouse at Dungeness, on the English coast, since 1862, and the light is said to possess more power of penetration than any other light.

From these and other cursory observations of the recent developments of magneto-electricity, flattering promises rise up in the contemplation of its future.

The steam-engine is hardly eighty years old, and the magneto-electric machine hardly thirty. It is only about forty years since the steam-engine was fairly appreciated, and hardly a decade since the magneto-electric machine was duly recognised in the family of practical mechanics, and if its future career should be commensurate with its past, it will take high rank among the great engines of human progress.

Some ingenious contrivances have been made with a view to prevent the local influence of iron in ships on the mariner's compass, and especially for use in iron-clad ships. These are in connection with the water compasses, in which the needle swings in a liquid, and the box so elevated above the mass of iron in the ship as to be beyond its influence, while the deviations of the needle may be observed from below.

In one instance, it is asserted that a peculiar arrangement of wires, conveying an electric current, operates so as to completely intercept local influences, and not interfere with that of the earth or produce any local effect of its own. The office has had no verification of this improvement.

In concluding this report I am impelled to present in prominent relief the important fact that, although the country has been engaged in a war which would have seemed to tax to the utmost all its energies, the applications for patents for the last year have been equalled in only two former years; and yet one half of our territory, shrouded in the cloud of rebellion, has contributed nothing to invention or human improvement.

The institution which has blighted that portion of the republic has long since recorded in this office its adverse influence to the arts and civilization. It appears that in the year 1857 there were granted to citizens of Massachusetts 421 patents, being a proportion of one to a population of 2,362. In the same year there were granted to citizens of Virginia 58 patents, a proportion of one to 24,511; to North Carolina 14 patents, a proportion of one to 62,064; and to South Carolina 12, a proportion of one to 55,708.

Labour being degraded in these States, there was no stimulus to mechanical activity; and as labour-saving machines were supposed to have the effect of supplanting and diminishing the value of slaves, improvements were regarded as injurious to the paramount interest of the State. It was only by unparalleled efforts that a northern inventor succeeded in introducing into the cotton States the gin, which added a hundredfold to their productiveness and value. This invention is an example of the benefit which the South will derive from new arts to be applied to her peculiar climate and products.*

The imagination fails to conceive of the happy future in store for this country when its fairest portion shall be regenerated by the adoption of a just system of labour, and conquered by free industry; when its land, by this change, shall, according to the remarkable estimates of Mr. Walker, have an increased value of over six billions of dollars; and when a whole race shall be taught to think, contrive, and create. The richest field of invention, with its fruits of wealth and prosperity, will then be opened that ever occupied the faculties of man. The visions of Virgil and Milton will be realised, and

> "Time will run back and fetch the age of gold."

D. P. HOLLOWAY, COMMISSIONER.

---

* In an interesting work lately published, entitled "In the Tropics, by a Settler in Santo Domingo," the author says:—

"Those who say the treasures of the tropics are to be best won by the brute force of ignorant labour cannot have studied with sufficient patience the march of invention.

"Intelligent labourers—men who know how to make wood and iron perform the severest part, to the sparing of human sinews—men who can work steam in harness—these are what is wanted here.

"Under the warm sun of the south *intelligent men and machinery will yet open the grandest field of civilization ever realised.*

"Even in such a small matter as hoeing a cornfield this is illustrated. Without violent labour I do as much clearing in a short forenoon with my little donkey cultivator as three good field hands in a whole day, and do the work much more effectually. Rating the donkey and myself as equal to a pair of Dominicians, the cultivator, which neither eats, sulks, nor runs away (to which as a class they are subject), counts for four common hands, which are subject to all those defects. The cultivator, I repeat, counts for four labourers, and asks no wages."

CORRESPONDENCE.

THE MALTA AND ALEXANDRIA CABLE.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—The following item is included in the Estimates of the House of Commons for the current year—£680 for the Malta and Alexandria Telegraph. Taking into consideration the enormous traffic and consequently large receipts on the above line, it appears to me inexplicable that the country should be called upon to contribute towards its maintenance. The income, I believe, exceeds considerably £2,000 per week, or £104,000 per annum, but I cannot find that any portion of this large amount has found its way into the Treasury. The cable cost the country upwards of half a million of money!—Yours, &c., ONE OF THE PUBLIC.

TOADYING CRITICISM.—CULLEY'S HANDBOOK.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—I have been vastly amused by a small criticism in the *Practical Mechanics' Journal*, of 1st July, on a book which all of us have admired, and most of us profited by. The author of the dozen lines—(I wonder he did not expand it a little with adjectives)—after subduing his praise by telling us that no good books on telegraphy exist in English, says:—"Our English telegraph engineers, generally, do not possess the sound rudimentary training in mathematics and physics, including *chemistry* (!), which are indispensable to clear authorship on this complex subject, and which is given in Germany, through its *magnificent* system of education in the gymnasia and universities, to every German engineer. A very small proportion of English engineers, in any branch of the profession, possess an university degree of any sort, unless it be some D.C.L., or LL.D., too often the tribute of toadyism rather than the proof of scientific knowledge."

An opinion so erudite in itself, and, doubtless, so pleasing to the *modest* German engineers, must necessarily be highly gratifying to English electricians—the inventors and discoverers of seventy-five per cent. of the existing electrical laws and telegraph systems—therefore I call your attention to it.

Probably if the Germanised critic of the *Practical Mechanics' Journal* had a little more intimate knowledge of the senseless dissipation and supreme humbug and Barnumism of the "magnificent system" with which he is in extacies, he would next time look in another direction for inspiration for his "lines."—Yours, &c., WILBERFORCE PETERS.

London.

THE PREVENTION OF RAILWAY ACCIDENTS.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—Having perused your observations on railway accidents, in the *Telegraphic Journal* of 2nd inst., No. 27, I deem it may be of interest to you to receive information upon the means employed on some of the railways in France to prevent accidents, by the use of Mr. Edward Tyer's electric signals.

You will find enclosed a list of thirty-eight stations on the Paris, Lyons, and Mediterranean lines, some of which have been in continual operation since June, 1856, and the others in progression. Ten are employed on the Eastern (Paris and Strasburg) line, and have given satisfaction, no accident having occurred where they are placed.

I enclose printed directions, published under a decision of the Minister of Public Works, and signed by the director of the Paris and Lyons Railway, which are given to the parties under whose directions these machines are placed. You will also find a list of the stations on the Paris and Lyons Railway where they are established, and where no accident has ever occurred.—I am, Sir, yours truly,

Paris, July 4, 1864. JAMES POWER.

NOTE SUR L'EMPLOI DES APPAREILS À SIGNAUX ÉLECTRIQUES POUR CONJURER LES ACCIDENTS SUR LES CHEMINS DE FER. SYSTÈME TYER.

Le chemin de fer de Paris à Lyon, sous la direction du chef de mouvement, M. Poirée, les a employés en 1856 et 1857, aux gares de Paris et de la Banlieu, ainsi qu'aux tunnels de Blaisy et de Perrache, où ces appareils sont en operation constante depuis.

A Blaisy, deux appareils ont été installés le 1 Juin, 1856, l'un à chaque entrée du tunnel qui est d'une longueur de 4,100 métres, avec pente de 0.004m. un au poste de Blaisy, l'autre au poste de Baulme la Roche; ils ont pour but d'empècher de laisser s'engager deux trains à la suite l'un de l'autre sous le tunnel; on ne laisse entrer un train que lorsque l'on sait par les indications des appareils, que le train qui précedes est bien sorti du tunnel.

Au tunnel de St. Irénée, qui separe les gares de Lyon, vaise et Perrache, un appareil a été installé à vaise et un autre à Perrache le 1 Septembre, 1857. Ce tunnel a 2,100 mètres de longueur avec pente de 0.003m.

Bien que ces appareils n'aient pas été employés sur le chemin de fer de Lyon pour prévenir les rencontres de trains, dans les courbes et tranchées profondes, il est indubitable que dans cette circonstance, ces appareils seraient de la plus grande utilité.

Les appareils sont installés dans les gares suivantes depuis le 1 Mars, 1857, jusqu'à Melun et les autres successivement, et ont pour but d'empêcher deux trains, de s'engager à la fois sur la même voie dans l'intervale qui separe deux postes consécutifs:—Gare de Paris, Bercy, Charenton, Maison d'Alfort, Avenue de Choisy le Roi, Villeneuve St. Georges, Mongeron, Brunoy, Combs-la-Ville, Lieu Saint, Cesson, Melun, Bois le Roi, Fontainebleau, Thomery, Moret, Darcey, Gissey, Boux, Verrey, Tercey, Blaisy Bas, Baulme la Roche, Malain, Beuchail, Velars, Plombières, Dijon (Chartreux), Dijon (Misericarde), Dijon (Bifurcation), Vaise, Perrache. Sur la ligne de Toulon, 2; au Souterrain de la Nerthe, 2; ditto de l'Ollioule, 2.

Paris, Octobre 31, 1861.

Au mois de Juillet, 1862.—2 appareils simples ont été installés pour le Souterrain de Courzon (Loire), Section du Bourbonnais.

Janvier, 1861.—Chemin de fer de l'Est, 8 appareils simples.
Ditto ditto 2 ditto

EXPERIMENTS ON THE PNEUMATIC SYSTEM.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—In your last number there appeared a long account of experiments made at Liverpool on the pneumatic system, quoted from one of the daily papers of that town, and to which you have appended the following remark: "We do not hold ourselves responsible for the statements contained therein." It is not often that one reads in a public paper statements so utterly contemptible as those contained in the account in question. The *inventor* and patentee of the system, Mr. Latimer Clark, is ignored, his name not being even mentioned by the "*chiel*" *intitioned* "*to tak' notes and print 'em.*" I hope that the *Telegraphic Journal* will some day enable its readers to learn the true history of this valuable invention.—Yours, &c.,

July 7, 1864. A LOVER OF FAIR PLAY.

JOINTS IN TELEGRAPH CORES.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—As one having had some experience in the making and testing of joints, and the speedy failure of joints when slovenly and imperfectly made, as was the case with the first Atlantic cable, permit me to offer a few remarks upon the subject. I have generally found that when the insulation of subterranean gutta-percha covered wires is impaired it is owing to the defection of a joint imperfectly made. Anyone who will take the trouble to look at the joints in the covered wires when they have been taken out from under the pavements of the metropolis for repairs, can easily satisfy himself upon the point. The coatings of the joint will be found loose and rotten, while the other portions of the wire are in an excellent state of preservation. I believe, like your correspondent "A. J. T.," that no efficient and durable joints can be made in the insulating substances hitherto introduced, except pure gutta-percha and masticated india-rubber. The absence of homogeneousness in every other material renders a sound joint impracticable, however well the machine-made portions thereof may test. The lamentable results of imperfect joints will be seen from the following quotation from the Report of the Government Committee on Telegraphs:—

"Was not the cable cut up into a great many lengths at Keyham, at Greenwich, and on board the Agamemnon, during the different trips?—No doubt there was a great deal too much recklessness in cutting the cable from time to time; that is to say, if a test was wanted, the first thing was to call for a person to cut the cable and begin to test, and then it had to be joined up again.

"Did not they very frequently, in testing the cable, prick for the wire?—That was done occasionally, I am aware, but in very many instances there was a positive cut. I have been informed by Captain Kell that the cable must have been cut into at least a hundred pieces at one time or other. Either from that cause, or from some other cause, this fearful result has taken place which is exhibited by these four joints—(*producing the same*)—which have been cobbled up again. I do not know whether they were in the original cable, or whether they were the result of cutting, but those are joints which I have taken out of a portion of the cable.

"Professor WHEATSTONE: Before the cable was submerged?—Yes, these have never been submerged.

"CHAIRMAN: What portion of the cable were those joints taken from?—They were taken out of the portion of the cable manufactured by Messrs. Newall & Co.; but I must not be understood from that to state, by any means, that they were made by Messrs. Newall. I cannot identify by whom they were made, but I can state that they were in that portion of the cable.

"Mr. VARLEY: How can you state that?—I can state that from the fact that that is flattened hemp, whereas in Messrs. Glass & Elliot's cable the hemp is spun, and then laid into strands; that is the reason I can identify it.

"CHAIRMAN: Newall's was flattened hemp?—Yes, laid flat round. Glass, Elliot & Co. laid theirs in strands round, and that enables me to

identify it. I have placed a properly made joint by the side, to show the contrast.

"Mr. VARLEY: It is very possible that a joint of this defective description may account for the sudden cessation of continuity, and its reappearance afterwards when the cable got to the bottom, owing to its separation by the stretching of the cable, and then coming together again.

"Mr. SAWARD: We have been assured by competent persons who have specially examined the cable on behalf of the company, that the slight defects which I have mentioned as existing before the cable was laid, were increased after the cable was down by the injudicious use of battery power, and the cable now lies in a state in which, although it may again, by great care, perhaps be got to work once more to a very moderate extent, can scarcely be hoped ever to fulfil the expectations which arose regarding it from the working after it was first laid.

"CHAIRMAN: Are you aware whether the statement made by Mr. Chatterton was correct, namely, that the servants of the Gutta Percha Company, who were sent to the contractor's works to make the joints, were sent away because they made the joints too slowly?—I am not aware of it; certainly if I had been aware of it I should have done all in my power to prevent it."

Your obedient servant,

July 6, 1862. JOHN NELSON.

TELEGRAPHIC NEWS.

THE ELECTRIC AND INTERNATIONAL DRAMATIC CLUB.—The members of the above club intend giving an entertainment in aid of one of their sick members on the 14th proximo, at the Cabinet Theatre, King's Cross. The following pieces will be performed:—"The Rent Day," "Love in Humble Life," and "A Rough Diamond."

MAGNETIC TELEGRAPH COMPANY.—Mr. W. Wright, the winner of the London clerks' in charge challenge cup, having resigned that prize for further competition, a second handicap took place at Sydenham on Saturday last, which resulted as follows:—Chamberlain, 1st; Manning, 2nd; Wild, 3rd. Won by 1½ yards; Wild being beaten by a foot for second place.

TELEGRAPHY IN THE EAST.—Our own correspondent writes from Pera on the 22nd of June, as follows:—"Colonel Patrick Stewart is expected here about the 15th of July. Colonel Goldsmith, and Mr. Kersting, assistant superintendent, left Bagdad on the 19th of May on a semi-official tour of inspection of the Turkish lines between that place and Scutari. A Turkish engineer accompanies them. They are expected here about the beginning of August."

THE GLASGOW, CANTYRE, AND GENERAL TELEGRAPH COMPANY (LIMITED).—On the 16th of February last a public meeting of merchants, shipowners, &c., was held in the Underwriter's Room of the Royal Exchange, for the purpose of taking into consideration the scheme brought forward by Mr. John Kincaid to establish telegraphic communication between Glasgow, the Mull of Cantyre, and all intermediate places. After some discussion a committee was formed for the purpose of carrying out the object of the meeting; and since then Mr. N. Holmes, of the Universal Private Telegraph Company, has been indefatigable in his exertions to meet the wishes of the committee. We are now enabled to state that the undertaking has assumed a definite shape, and that a company has been formed, entitled, "The Glasgow, Cantyre, and General Telegraph Company (Limited)," for the purpose of carrying out the idea. We also understand that the new company has already received sufficient encouragement from the commercial public to induce them to enter into contracts for the formation of the line to Rothesay and Campbeltown, and in the course of three weeks it is confidently expected to be open to the former town, and by the middle of August to the latter. Starting from Glasgow, the line proceeds direct to Helensburgh, and, crossing the Gareloch at Row, it stretches from thence to Kilcreggan and on to Cove. Crossing Lochlong at the latter place, it proceeds by Blairmore round to Kilmun, and onwards by Loch Eck, crossing Lockfyne at Craigans, and from there to Inverary, and from Inverary down by Lochgilphead to Campbeltown. In order to connect Rothesay, a branch leaves the main line at Kilmun. Crossing the bridge there, it passes on to Dunoon, and onwards by Toward Point, where it crosses by a submarine wire from Ardine Point to Ardbeg, and on to Rothesay. It is also intended, we understand, to form a connection with Oban, either by way of Ardrishaig or Inverary. The above may properly be considered the commercial part of the undertaking; but another impotant feature is yet to be determined upon, viz., the extension of the line to Cumbrae, Pladda, Lamlash, and Cantyre Lighthouse, as explained by Mr. Kincaid at the public meeting referred to. This portion of the line will be most important to the shipping interest, because all vessels in distress, and in want of assistance, or wind-bound in Lamlash Bay, or in want of a tug-steamer, can easily telegraph from any of the above-named stations. It is a well-known fact to the Uunderwriters that ships with cargoes of great value have gone ashore on the Cantyre coast and become complete wrecks, although the circumstance was unknown in Glasgow for some days after the occurrence. With the telegraph in operation, it might reasonably be expected that assistance will at all times be forthcoming within a few hours, and through this means many lives and much valuable property may be saved. The telegraphing of inward bound American and other foreign steamers and sailing ships will also be of the utmost importance to all parties interested in them. It will also enable the proprietors of tugs to maintain constant communication with their boats at the various points of call. To effect these objects, and before proceeding with that portion of the undertaking, the company will require guarantees for three years from parties interested, that the revenue of this branch shall amount to a fair per centage on the capital expended. As this proposal seems perfectly reasonable in the circumstances, shipowners and others interested in the matter will no doubt see the propriety of making terms with the company without delay, as the work can be done at much less expense while the commercial portion of the line is in progress than it can be afterwards, if it is specially undertaken. We are glad to learn that the local authorities of Greenock have made arrangements with the company for the use of the telegraph, and that a reasonable guarantee has been given for the value of the service required. It must be a matter of much gratification to Mr. Kincaid to find that the scheme which he propounded upwards of eleven years ago, and which was then considered impracticable by many people, is now in a fair way of being realised.—*Glasgow Daily Herald.*

THE INDIAN LINE OF TELEGRAPH.—The special correspondent of the *Levant Herald*, writing from Bagdad, under date May 27, thus adverts to the condition of the Indian line of telegraph:—"The affairs of this important pashalic, at all times of great moment to Turkey, are rendered now additionally interesting to England and English readers by the fact of the new line of Indian telegraph passing through a considerable section of it. I regret, therefore, to have to report that the present state of things is eminently unsatisfactory; the construction of the telegraph is in consequence impeded, and it is doubtful when it may be resumed. The immediate cause of this untoward *imbroglio* is the disagreement of the Governor-General of Bagdad, Namyk Pasha, with the numerous and powerful tribe of Montefik, and the consequent revolt of the latter. They have been at issue for a long time, but the governor, at length, by way of humiliating the scheik, and weakening his *prestige*, decided to abolish the title of scheik altogether, and nominate him as *caimacam*. Upon this the seething dislike broke out into active and enraged hostility. When the governor saw the impolicy of the course taken with respect to the proposed infringement of the time-honoured dignity of scheik, he withdrew his order; but this was merely temporising. General belief here attributes the conduct of the governor, not so much to his own deliberate intention and resolve, as to the sinister recommendation of his *kehaja*, a local *mufti*, who unfortunately exercises great influence with the pasha. In withdrawing the order after it was once issued feebleness was evinced, and the next step showed corresponding rashness. Instead of resorting to and exhausting every possible means of conciliation the governor decided to send an armed expedition against the tribe. The expedition has accordingly set forth, and the conviction is here, that if it do not meet with disaster the victory it will reap will be but a barren one. The celebrated Ghiosukgli Reschid Pasha, when he was governor of this pashalic, waged against this same tribe a war of several years duration, but at length, notwithstanding his power and *prestige*, was obliged to resort to conciliatory measures in order to pacify and subjugate them. He found these the only efficacious means. The Montefiks are a powerful tribe, they can draw others to their standard, and the passage of the electric wire in their midst makes them additionally conscious of their importance and their power. Had the advice of the English Consul-General at Bagdad, Colonel Kemball, been listened to in this emergency, as it should have been, this difficulty might have been obviated; but his experienced and sound advice was not followed. The javelin is now thrown, and if the expedition fail the *prestige* of the Turkish Government will receive a rude shock, and a risk would be run of an insurrection at Bagdad. The obstinacy and ignorance of local pashas, the intrigues of their subordinates, the revolt of a powerful semi-Arab tribe, turbulent and warlike, although the scene be laid in the important and historic pashalic of Bagdad, are of moment only, people might generally say, to the Turkish Government, who rule, or should rule, the uneasy province. But as the theatre of disturbance is also the line of route of the Anglo-Indian telegraph, England is at the same time keenly concerned in the matter, and it should be made concise and clear to all whom it may concern. As the shortest route from Bussorah to Bagdad the line passes through the territory of the Montefik tribe; and if the construction of the line were left to the English managers and engineers there is not the shadow of a doubt but that the tribes would allow the works to proceed unmolested, and would aid, probably, rather than obstruct. But they will not allow the Turks to make the line, and Namyk Pasha, standing upon an airy and illusory pedestal of dignity, insists that, as it is in Turkish territory, Turks, and Turks only, shall construct it. The English undoubtedly are willing to subsidise the Arabs—but what matter? What possible injury could accrue to Turkey? None whatever. The greatest advantage, on the contrary—peace in her boundaries, and the orderly progress to rapid completion of one of the greatest international enterprises of the age. If the Turkish Governor of Bagdad were a man of cultivation, sense, and experience, instead of setting up at every moment, in season and out of season, an absurd affectation of dignity and authority, he would, like a sensible man, allow the English engineers to construct the line quietly. The Arabs would remain at peace, and a great end would be attained. In a word, the practical details must be left substantially in English hands, or the consequences will be inadequate and vexatious in the extreme. Meanwhile between Bussorah and Bagdad the Montefiks and the authorities are at open war, and there seems no probability of the line being completed through that tract of country until

autumn—if then. To rely upon the present line, therefore, as far as the disturbed territory in question is concerned, would never do. In the East, more perhaps than elsewhere, it is necessary to have two strings to your bow. Thus another line, of a more roundabout character, no doubt, but which will avoid the disturbed territory altogether, is in active process of construction. By a treaty between the Persian and English Goverments of October last it was decided that a line should be constructed by the Persian Government from Bushire, on the Persian Gulf, one of the landing points of the cable, viâ Kazeroon, Shiras, Movighant, Koomshah, Ispahan, Kashan, Koom, Tehran, Hamadan, Kermanshah, and Khanakeen, to Bagdad. The distance between Bushire and Khanakeen is about 1,100 miles. This line is expected to be open by the 1st of August next, but I much doubt whether the Ottoman Government will be ready by that time. There is nothing like a frank and sincere appeal to head-quarters. I wish the Porte would look to this. Instead of having an important district in turbulent revolt, and a great international undertaking checked and frustrated, by the peddling self-sufficiency and incompetence of a local magnate of an obsolete school, the most perfect peace might reign there, and the electric wire between Bussorah and Bagdad be in a condition to flash news to Constantinople, without interruption, before autumn sets in."

THE INTER-CONTINENTAL TELEGRAPH.—Subjoined is a communication regarding the above project, which appeared in the *Times* of the 4th inst. :—

"Sir,—In reference to the paragraph in your article of the 27th ult. on the question of the inter-colonial telegraph, will you permit me to say that the fact of a concession having been granted to Mr. Collins is somewhat doubtful. That the Russian Government are prepared to grant such a concession when the capital has been found I have every reason to believe, but it is absolutely necessary that some survey of the district through which the line is to pass should be made before any capitalists can be advised to risk their money in a project of, at present, doubtful aspect. A few years ago the engineer of the Russian Government in control of the telegraphs reported dead against the practicability of taking a line through the region north of the Amoor, on the ground that it would be impossible to maintain stations in such inhospitable regions (and that some few stations must be maintained can, I think, admit of no doubt), and he recommended that the route by the Aleutian islands should be adopted in order to reach the American continent. Since that time it would appear that the Russian Government have given up the idea of carrying this out, probably because their possessions in Russian America do not justify the outlay, but when we talk of constructing a line by this route it behoves us to take into consideration all the evidence hitherto collected on the subject. For myself, I am inclined to think that the line would offer fewer obstacles than some people anticipate, but I am bound to admit that those engineers who are opposed to its practicability advance reasons that are entitled to a hearing. Let us, in the interests of telegraphic progress, first demand such a survey of the north-east coast of Russia, and the north-west coast of America as may satisfy us of the practicability of the line, and then let Mr. Collins, or any one else, try and carry it out. As for speed, there is no reason why a message should take longer by this route than by the Atlantic (when laid), although, of course, the profit resulting from a message passing over 16,000 miles of wires, representing a capital of at least £2,000,000, must be somewhat less than that which will arise from the Atlantic line, supposing that it is successfully submerged next summer. Your obedient servant, C. E."

ANGLO-INDIAN TELEGRAPH.—With regard to the above line we find the following paragraph in the last *Bombay Gazette*:—" Up to the very moment when the ships of the Expedition dropped anchor off Fao, where the British portion of the telegraph to India terminates, Colonel Stewart confidently expected that he would immediately be in direct communication by telegraph with India on one side and England on the other,—such confidence did he feel that the important part of the operations for bringing this about, which had been entrusted to himself, had been efficiently executed; and so hopeful was he that, in view of the immense importance of the work, the Turks would for once have shown a little energy in doing their part, more especially as he knew that if they had only given a very moderate amount of assistance and support to the British officers and employés who had been sent to their aid, the work would almost have been done for them. But alas for faith, however weak, in anything Turkish! We might as well expect the leopard to change his spots, or the Ethiopean his skin, as the Turk to awake from the indolence and lethargy belonging to wasting muscles and loosening sinews which have fallen upon him in these later times. One part of Colonel Stewart's expectation was amply fulfilled: he did find himself in rapid and regular communication with India through the cable that had just been laid down; but when he hoped to be able to send on to England the news, not half an hour old, which had sped along it, he was filled with disappointment, for not only did nearly 200 miles of the Turkish line through Mesopotamia remain to be completed, but there seemed no hope that it could be completed for many months to come; and, moreover, a very important part of the line already erected by the Turkish Government between Bagdad and Constantinople was broken down to an unknown extent. Rebellion of the Arab tribes was the cause of these 200 miles in Mesopotamia remaining incomplete, and that rebellion was the result of the mistaken policy conceived by, and obstinately persisted in, in spite of repeated British warning as to the necessary result, by Namyk, the Pasha of Bagdad. His only course now is either to yield to the demands of the insurgents, which, indeed, do not seem to be very unreasonable, or else to crush them with overwhelming force, and maintain the supremacy thus regained (if that can be said to be regained which was never really possessed before) at the point of the bayonet. The former he may do—indeed, if he would have accepted advice from the British representative, Colonel Kemball, it might have been done long ago without any loss of dignity; the latter he cannot do, for though there is no lack of Turkish troops in the pashalik of Bagdad, yet they can scarcely be made available at a single point without exposing all the others to the dangers of revolt or invasion."

THE AMERICAN ARMY TELEGRAPH.—The correspondent of the *New York Times* gives the following account of the army telegraph:—"The wires of the army telegraph are insulated, and may be unrolled with great rapidity from a winch in a waggon constructed for the purpose. As the waggon moves forward, the wire is left to trail on the ground, or is placed upon light, portable poles, with pointed ends for thrusting into the soil, or is simply rested upon branches of trees by the roadside, as it threads its way through all the corps' head-quarters, and converges from every direction to the position of the general commanding. When the army moves, the wire is taken up by the winch just as quickly as it was laid, and is ready for use at the next stopping-place."

FRENCH ASSOCIATION FOR THE ADVANCEMENT OF ASTRONOMICAL AND METEOROLOGICAL SCIENCE.—This new society is now completely organised, and in active operation, a cordial understanding existing between the president, M. Le Verrier, and the chiefs of Greenwich Observatory and the Meteorologic Office, in London. The following are the directors of the association:—Messieurs Le Verrier, Michel Chevalier, Le Doctor Conneau, Glais-Bizom, Payon, Vicomte de Vougy, Belgrand, L. Moucher, Serret, d'Abbadie, Baron, Barral, Marié, Davy, Renon, A. Sanson, Gaillot, et Wolf. The first meeting of the society took place a short time since, when the chair was occupied by M. Le Verrier, the director of the Imperial Observatory, who was supported by Dr. Conneau, and M. Glais-Bizom, as vice-presidents. Just as business was about to commence, a telegraphic message was received from St. Petersburg, congratulating the new association on its formation and first meeting. M. Le Verrier addressed the associated members on the present desiderata in astronomical science, the proposed establishment of observatories in the principal towns in the south of France, the services rendered to navigation by meteorological telegraphy, and those which it may render to agriculture. M. Renon, the secretary of the Meteorological Society of France, presented a report on the prizes to be offered in meteorology, which are as follows:—A grand prize of the value of 4,000f. for the best general memoir, printed or written, in French or any other language, on the general movements of the atmosphere, with the view to the foretelling of tempests; the memoirs to be sent to the secretary of the association, at the Imperial Observatory, Paris, before the 31st December, 1865; three prizes of 500f. each, for observations made in places little known in that respect, or taken at sea; these to be sent to the association before the close of the present year. Models and portions of the great telescope, now being constructed for the association by M. Léon Foucault, were exhibited, together with the fine block of glass destined to be employed in the formation of the great lens.

ANGLO-INDIAN TELEGRAPH.

THE insurrection of the Montefic Arabs is now entirely quelled, and the state of the disturbed district between Diwanyeh and Korneh is now such that the telegraphic works can be resumed, but it will not be possible to make much progress until the autumn, as the men can do very little work during the present hot and unhealthy season. Colonel Goldsmid arrived at Mosul (the site of the ancient city of Nineveh) early last month, on his way to Constantinople to report on the condition of the line through Asia Minor. He will then meet Colonel Stewart, C.B., who left Bombay by the mail of the 24th June. It is earnestly to be hoped that strenuous exertions will be made by the Government to provide a proper service of English clerks at the chief stations between Scutari and Fao, without which it is utterly impossible that the enormous commercial traffic which may be looked for directly the Anglo-Indian line is opened can be efficiently performed. The technical character of the messages between merchants in this country and India, the quotation of prices of various kinds of stock and goods, the names of vessels, and many other details which will naturally occur to any one accustomed to the daily routine of a telegraphic instrument room, will otherwise be so mangled in transmission as to render the line more an agent of confusion than of utility, and the result of a bad beginning will retard the advance of the traffic afterwards more than the Turkish Government (who are so largely interested in obtaining good returns) can probably conceive.

By far the greater part of the messages will be in the English language; and it is absurd to suppose that any Turkish official, however much he may have studied it, can master the names and expressions of mercantile dealings sufficiently to cope with the business in a satisfactory manner.

The Persian line between Teheran, Ispahan, Shiraz, and Bushire, is proceeding rapidly, and will most likely be (in connection with the Russian line *viâ* Tiflis and Tabriz) the first by which the Persian Gulf cable is worked through to India.

FORCE AND FORM.

CONTRIBUTED BY B. M.

II.

THIS view of matter, as force in a form, no doubt will be called visionary and fanciful, but there are fewer assumptions by far in this than in any other yet propounded. It cannot be said to be absolutely new, for it is at least a century old; but of course it is comparatively new when compared to the generally-received theory, namely,—the hard, unyielding particle, which is neither compressible, expansible, nor divisible, in fact is unalterable, according to the theory. Of course each particle, according to its kind, must have a certain size and form to be a finite entity at all. It is easily perceived how this theory has grown up out of our sensations, with some slight shaping by the intellect from time to time. A stone is hard to the touch, even of a savage, and if he can be supposed to speculate about the ultimates of matter, he would arrive at them by the simplest means, namely, by division, and when he had divided the supposed stone into the smallest portions possible, either in fact or imagination, he would say there is your ultimate particle, and he would be just saying what our philosophers have said, and are saying. That being done, then, as the necessities of the case arose, these particles could be endowed with properties to suit all circumstances, such as attraction and repulsion, difference of shape and size, &c. If angular, they would become solids; if spherical, they would become fluids of the most mobile kind, and with due admixture, liquids of every degree of limpidity, and so on as every new condition arose, a new supposition. But can that be called a theory out of which nothing spontaneously grows? It looks like a patchwork of after-thoughts; there is no prevoyance whatever; yet this is our present theory of matter. Certainly it is the first rude beginning of a theory which must be pruned and dressed into shape, and cultivated into life by experience.

But it is said, "the atomic theory must be true, for see what results have grown out of it in chemistry!" This is an error. The theory of chemical equivalents has nothing whatever to do with the ultimate particles or atoms of matter.

The theory of the ultimates of matter can be ignored altogether, yet that of chemical equivalents will stand good; for it is simply quantitative, and has nothing to do with ultimates at all. Let us take this ultimate particle or atom as at present understood, and see what of reason we can get out of it. It is a little unchangeable, impenetrable piece of matter, with an atmosphere of force around it. Let us take the nucleus first, an unchangeable, impenetrable piece of matter. Now to be matter at all it must have length, breadth, and thickness, and then follows the necessity that, however small it may be supposed to be, it can be halved. All that can be said to this is, that by this supposition it is unchangeable; but I answer, your supposition is untenable then, for it can only be based on this, that an ultimate atom is the hardest thing in nature, and therefore, if even we had senses and instruments fine enough, we could not find a material hard enough to divide it; but do we not divide diamond, which is the hardest material we know of; and if diamond will cut diamond, why should not atom cut atom? But I hold it to be untenable on another ground. I take it as an axiom, that whatever reason shows to be possible, *is possible;* therefore your ultimate particle can be divided *ad infinitum*, which makes it no ultimate particle at all. Now let us take the surrounding atmosphere of force, which is added to this hard nucleus to make an atom. An atmosphere of force. What is force? Simply that which is always producing motion, or in effort to produce it. Then how can a force exist without a contenant? It cannot exist at all: it would be simply dissipated, annihilated. Then this atmosphere of power or force must of necessity have a bounding form, or annihilation ensues from the very nature of force, which is perpetual activity or effort, and without a contenant would be perpetual activity to infinity; but that is not possible, for the forces we are treating of are finite, for they pertain to finite matter, therefore each force must have its limit of potency, and if a limit of potency, then *there* will be its bounding form, consequently every force must of necessity have its bounding form. But we have seen that the hard nucleus inside this atmosphere of force approaches to the vanishing point by simple division, let it then vanish, and what have we: simply *force in a form.* Now what have we lost by expelling this piece of hard, untractable brute matter, which is the only piece of dead, inert matter that I know of. Let it go. There is one obstacle less to our understanding this living and moving world of matter, and the higher lives that breathe through it.

Now let us examine the atom we have obtained by this sublimation. *A force in a form.* A simple force in a form must of necessity be dynamic, it can only become static by being opposed by an equal force, neutralizing it, and of course it is simple force in a form, without complications, that we must first consider; then that form must be the form of its motion, which in this case will be a simple sphere of potency, whose centre is its starting-point from within and its termination from without. A point then is the nisus of all motion, and consequently of all force. This hardly needs to be stated, for every one sees that all motion must start from a point, and end in a point. What says geometry? The science of mechanical forms; the first and simplest of all sciences, consequently the most perfected; it says that all figures and forms have their origin in a point: point, line, surface, full form; and moreover it says, that a line is produced by the motion of a point, a surface by the motion of a line, and a solid by the motion of a surface. This is a mechanical way of stating it, certainly, but geometry is the science of mechanics, which deals much in straight lines, but nature sparingly, if at all. Form has been known these many centuries to have its origin in a point; yes, even before the old school-master, Euclid, wrote about it; and to me it is as clear, that force also begins in a point, and if you say it is not so, then show me how it can be otherwise; till then I shall take it as proved. What becomes of the objection so fatal to the hard nucleus? You cannot divide our atom; it is a force in act, whose centre of potency is a point, and limit of potency its form; you cannot divide it unless you divide it in its perpetual origin, which is a point; but from the nature of a point, that is not possible. But by the induction of other forces there may be less or more of activity and consequent increase or diminution in our atom; but this is claimed for the atmosphere of the atom with the hard nucleus, else there could be no such thing as expansion or contraction in matter.

But matter and force, according to the present theory, are considered two separate and distinct things. We, on the contrary, consider force the essence of matter, and that the form of this force gives matter all its properties, discernible to the eye, and many to the touch. This is a wide difference, and one pregnant with many results, and especially to the better understanding of electricity and magnetism, and from these the greater part of our confirmations by experience will be brought, as to the forms of motion and many other particulars.

We will enumerate some of the known forces, to show by this theory how they act and re-act on each other in spheres and cyles, and to show that all matter is simply forces in static form, and that it is not made up of hard, unalterable, dead atoms, with force superadded. The forces we would name are these: attraction of cohesion, chemical affinity, gravity, heat, light, electricity, and magnetism. Attraction of cohesion is the drawing together of like to like; but chemical affinity is the drawing together of dissimilars; therefore, the resultant is altogether different to either of the forces uniting; as is shown in all chemical compounds. Gravity is the general sphere, which includes at least the foregoing, and seems to be in the inverse ratio of the activity of the combinations of atoms concerned; for if a substance be condensed or compressed, it retains absolutely the same gravity as it possessed before condensation or compression; but is relatively to bulk of greater gravity than before, and has given out some force, equivalent to the force applied, and has produced in lieu thereof a like equivalent of heat, and that force cannot be again restored, so far as we know, but by the application of a like amount of heat.

We speak of attraction and repulsion very glibly, as if after having said these words we knew all about what we meant by them; but it appears to me that we do not even give ourselves the trouble to try to know what we are meaning. Of course we can say, and do say, that attraction means a drawing to, and repulsion a thrusting away from; but that is just, in effect, saying nothing. The thing we really do want to know is, how can two things attract each other, for it is always mutual. Can we reduce it to some mechanical form, that it may be made understandable? for down to that sphere all things must be brought if we are thoroughly to comprehend them, for in it we live, and move, and have our being. What then is the how of this thing? Does it take place at a distance without anything intervening, or must there be a medium? Is it in straight lines, or in simple curves, or in spirals?

When one sets oneself seriously to think about it, one cannot imagine, that it can take place at a distance, for that would be obtaining an end without the means of a nexus; therefore there must at least be a medium. Then how can it be comprehended that two things can approach each other in a straight line by means of an inherent force in each? That they could be projected against each other by forces external to each in a straight line, may easily be comprehended, but not mutually drawn by their inherent forces. A simple curve is under the same difficulty of comprehension; but I think not so a spiral.

THE PREVENTION OF OUTRAGES IN RAILWAY CARRIAGES.

NEVER since the introduction of railways has the press recorded so many fearful misadventures as have occurred to passengers within the past twelve months. It is but a short time ago that all England was startled by the story of a desperate encounter with a maniac, in which inoffensive travellers were only spared merciless death by force of numbers. Since that date scarcely a day has passed without outrages of some kind having been attempted on lonely women travelling by the rail. Now it is our painful duty to chronicle one of the most barbarous murders on the North London Railway that ever disgraced the annals of a civilised country. On Saturday, the 9th instant, about three o'clock in the afternoon, Mr. Thomas Briggs, a gentleman sixty-nine years of age, well known in City circles, having for many years been connected with the banking establishment of Messrs. Robarts, Curtis, & Co., left the bank for the day, and proceeded to his niece's residence in Nelson-square, Peckham, where he dined. There he remained until half-past eight o'clock, and was seen into an omnibus in the Old Kent-road by the husband of the niece, Mr. Buckham, who parted from him in his usual good health and spirits. Before leaving he intimated that he would proceed to the City, and then take the train from Fenchurch-street Station for Hackney. He was almost a daily traveller on the line, and was well known by the railway servants. From the time of his getting into the omnibus in the Old Kent-road until his body was discovered on the line of the North London Railway nothing has been gleaned of his movements, or whether any one was in his company. At a quarter or twenty minutes past ten o'clock on Saturday evening, on the arrival at Hackney of the 9.45 train from Fenchurch-street Station, a gentleman called the attention of the guard to the state of a compartment of a first-class carriage (No. 69) in the train. He had opened the door at Hackney with the intention of getting in, and had placed his hand on one of the cushions, which he found to be covered with blood. The guard, on looking in, found such to be the fact. Not only were the cushions, but the floor, sides, and window were besmeared with blood; in some places there were pools. He also found inside the carriage a gentleman's hat, a walking stick, and a small leather bag. The guard at once took charge of the articles, and locked the door. Some ladies who were in the adjoining compartment noticed to the guard the circumstance that some blood had been spurted through the carriage window on to their dresses as the train came from Bow. The

guard at once telegraphed the discovery to Mr. Kebble, the station-master at Bow, and at the time an impression was entertained that some one had committed suicide, and had thrown himself out of the window of the carriage on to the line. About the same time that the above discovery was made, the driver and stoker of an engine which had been working the Hackney-wick and Stratford traffic, and which was returning from the Wick Station to the Bow locomotive works of the North London Railway, as they were approaching the railway-bridge over Ducket's Canal saw something lying on the six-feet way—the space between the up and down line. At first the driver thought it was a dog, but the stoker judged it to be a human being. The engine was stopped, and the stoker got down and went back along the line with a lamp. On coming up to the spot he discovered the body of a gentleman, saturated in blood, and apparently dead. A brutal murder had been committed, and the perpetrators of the atrocious crime have hitherto eluded the vigilance of the authorities.

The frequent occurrence of assaults and outrages in railway carriages has rendered travelling dangerous, and unless some means are speedily adopted whereby greater security can be ensured to passengers, the usefulness of our great locomotive highways will be seriously impaired. On the American, French, and Belgian railways the guards are able to pass up and down or through the trains, and to render any assistance that may be required; but on the English lines no system of communication exists between the passenger and the guard or driver. To this circumstance may be ascribed the many evils of which we complain. Communication there must be between caged-up *voyageurs* in a railway car and the official in charge. It is no longer to be tolerated that the honour of women is to be assailed, and the lives of venerable men to be sacrificed to the highwayman, because railway companies will not effect modern improvements in their rolling stock. At the present time our railway carriages possibly offer facilities to the criminal; and now that the work of the desperado has been begun, we cannot, considering the contagious character of vice, suppose that we have heard the last of these outrages.

It therefore becomes a matter of great importance that measures should be devised for the better security of railway travellers. On reference to another portion of our columns it will be seen that this subject is being debated in the daily press. All the writers agree that some system of communication between the guard and the passenger should be established. Various are the means proposed to attain this object: some of them are identical with the plan advocated by Mr. Owen Rowland in the *Mechanics' Magazine*, the *Railway Record*, and other papers, in 1846; but all of them prove immeasurably inapplicable when compared with the electric bell. There are many electrical inventions at the service of railway directors, but they will not be impressed into the service until some appalling catastrophe induces the public to demand their application. Electric bells are now employed in all the large hotels on the continent, and are being gradually adopted in this country. Their extreme simplicity and utility, and the innumerable purposes to which they can be applied, induce us to urge their employment as a means of signalling from the carriage to the guard of a train. It may be asking too much that the rolling stock of railway companies shall be altered, and made like that in use on continental lines; but we demand that, if it be impracticable to adopt a system whereby passengers will be able to summon immediate aid in case of danger, means be employed to enable the traveller to indicate to the guard of a railway train that his presence is required in a certain carriage so soon as it is possible to bring the train to a standstill. Were the electric wire employed it would be simply necessary to touch a button or a spring to effect the desired signal. In the adoption of this plan there are no mechanical difficulties to be overcome, no machinery to become deranged. A trifling outlay would thus establish a deterrent to the vicious, and a protection to the peaceful traveller, without impairing the value of the rolling stock. It has been alleged that a system of communication with the guard in charge of a train would prove an inducement to certain of the *genus homo* to complain of the most trivial circumstances, and thus occasion delay on a journey, and interfere with the regular working of the traffic. These objections are fallacious, and are advanced more in palliation of the tardiness of railway directors to effect improvements or alterations, than from fear of ungrounded complaints. The safety of the passenger from accident by the rail, or outrage on the rail, can be ensured by the adoption of adequate precautionary measures, and we hold the company culpable that neglects to afford all possible security to those who entrust their lives in the tearing, rattling team. The occurrence of Saturday last has created a painful sensation throughout the country. It is felt that the fate of the revered gentlemen, who was so barbarously destroyed when on the verge of three score years and ten, possibly awaits others. A common danger has been recognised; and it is the duty of all railway companies to, so far as practicable, avert the recurrence of these terrible atrocities.

A FRIENDLY SUGGESTION.

The main object of the managers of joint-stock companies, with few exceptions, is to obtain the largest possible dividend for shareholders. The disposition of the commercial world, in the eager struggle for wealth, is to set aside the claims to consideration and sympathy of those who possess no other privilege than that of working for a mere pittance. This leads to a condition in which the reciprocal interests of employer and employé become ignored; and from this state of indifference there is no appeal but to the consciences of those in whose power it is to induce a better state of things. It may, therefore, be in season to bring to mind a time-honoured custom which is calculated to counteract this tendency. Work, unrelieved by recreation, impairs the physical and mental energies of the human race, rendering the being unfit to perform efficiently his or her social obligations, and prematurely destroying the constitution so beautifully and wonderfully made. There are no harder working people on the face of the earth than the English; and no class of this people so many hours per diem employed as those engaged in telegraphy. Their labour is (pardon the paradox) constantly intermittent, and their opportunities for relaxation accordingly limited. Let any one who doubts the truthfulness of these observations visit the establishment of any telegraph company, and the appearance of pale, worn, sickly, stived-up manipulators will attest the statement. It is on behalf of these—the least in the employ of telegraph companies, if we may judge by the consideration they receive—that we have a word to say.

Nothing can be more desirable than that the great gulf which has hitherto separated the employer from the employé should be spanned by a viaduct of cordiality. No combination of circumstances has tended to effect this object so fully as the Volunteer movement. Here men of all grades and positions in society meet on an equal footing for a common purpose: the exercise to all is the same; the instructions, or, rather, the commands are given alike to patricians and plebeians, while the penalties for any breach of the regulations or neglect of duty admit of no distinction. Here the fraternal condition is fully realised; and we have yet to learn that any evil consequences have arisen upon this departure from the traditions which have so long prevailed, setting class against class, and rendering exclusive the intercourse of those occupying exalted positions in society. It has been urged when these views have been enunciated in the presence of persons possessing but

a limited knowledge of human nature (though the objection is as old as the hills) that familiarity induces a condition at variance with proper discipline. The fallacy of this plea has been met by a reference to the efficiency which the new national force has attained. We are anxious to extend the principle of cordiality between persons engaged in different branches of the telegraphic art, and to promote a more general intercourse between the principal and subordinate officers in the telegraph service. How is this to be effected? Not by unreasonable demands on the one part to be met by peremptory refusals on the other; rather by the patient consideration of the respective positions. It is not within our province to indicate any particular course of action—the means to be employed can be best determined according to locality and circumstances; but we have no hesitation in recommending for adoption the practices of other sections of the community, where they appear likely to conduce to the end in view.

It is customary in large manufacturing and other establishments for employers and employés to have an "outing" at least once a year. In the several trades these trips are variously denominated: the "bean feast," the "wayzgoose," the "annual excursion," are only different terms to express one and the same thing. These affairs generally prove a source of unmixed gratification to all who participate in them. Would the reader know the character of these gatherings? They generally comprise a trip to some rural spot by one of the many means of transit available to the public—a pleasure in itself. Arrived at the locality previously indicated, a well-spread table awaits the excursionists, at which the principal of the establishment or the head of the firm usually presides. When the temporal necessities of the party have been duly ministered to, the usual loyal toasts and pledges are given, which affords occasion for the expression of sentiment, and never fails to exercise a salutary influence. The employer avails himself of the opportunity to discourse kind words—they cost little, but are very valuable—and is met with expressions of regard or with tributes of gratitude from his employés, which not unfrequently show to each their mutual dependence, and tend more than anything else we know of to promote good feeling and harmony. The remaining portion of the day, perhaps, is spent in the enjoyment afforded by the sports of the field, boating, &c. The days of riotous and drunken revelry are over. No violations of peace or order occur, and all return to their ordinary avocations on the morrow wiser and better men.

This good custom has not yet met with recognition in the telegraph service. We have recorded several trips and holidays of clerks in telegraph companies, but these have been notable for the absence of those whose presence—not patronage—would have been a source of satisfaction, and would have given vitality to the proceedings. Even sheep like to hear the shepherd's voice. How much more, then, do men desire to be occasionally brought within the personal influence of those who are called upon to rule over them? Once a year, at any rate, the reserve and *haut-ton* of office might be cast aside, and directors, secretary, manager, engineer, and electrician might meet the humble workers in the same undertaking with beneficial results. Interchange of thought and feeling is productive of great good, and whoever ignores its advantages isolates himself from society, not without paying a heavy penalty for his folly. The officer (who cannot understand what clerks want holidays for, but who takes his two months' tour on the Continent every summer) may express the utmost contempt for the sentiments we have enunciated—may raise the shadows of objections, alleging the impracticability of these suggestions, urging that they are Utopian and unworthy of further consideration—but we leave the major portion of our readers to judge the value of our remarks, and to supplement our efforts at the board meeting, or otherwise, as opportunity offers. In this matter we must not be understood to advocate the patronage by one class in order to effect the degradation of the other; on the contrary, we insist that there are duties and responsibilities attaching to both the employer and the employé (and the superior officers in joint-stock concerns may be considered in the position of the former) which will in good time be fully acknowledged. In the meanwhile it will be well to perpetuate the custom to which we have adverted. We are not saying too much when we affirm that many orderly-minded men of means esteem it a privilege to invite their "hands" (we use conventional language, in which heads and hearts are never taken into account,) to an annual merry-making, and highly value a hearty response. Telegraphy is now a craft, and there is no reason why the practices of other businesses should not be adopted by those engaged in the transmission of intelligence. We commend this subject to the consideration of the directors and shareholders of our large telegraph companies; and whenever we learn that our recommendations are about to be realised we will undertake to give due publicity to the proceedings in these columns.

SMITH'S ELECTRIC TELL-TALE.

THE ordinary tell-tale or "pin" clock, although it secures the vigilance of a watchman in one portion of the building, cannot do more. It certainly cannot inform the master whether or not the man has gone his nightly rounds as he ought. That he has been watchful and attentive in any one hour is all that one clock can prove, and the employment of two or more is rather too costly an expedient to prove very popular. The accompanying engravings give an external elevation of a very simple and ingenious tell-tale, invented by Mr. Willoughby Smith, electrician to the Gutta-Percha Company, and manufactured by Mr. J Sax, of 108, Great Russell-street, Bedford-square. The principle of its action is simply this:—Let us suppose that in different parts of a large establishment, instead of expensive clocks, a number of old-fashioned hour-glasses were placed; let us suppose, further, that the watchman in going his rounds should turn all these glasses within the hour. It is obvious that, if any means could be devised by which the turning of each glass before it was run out could be registered, all the purposes of the best watchman's clock would be fulfilled. This registration is exactly what Messrs. Smith & Sax effect, but the registration takes place in the head office of the firm, and it is matter of impossibility in consequence to tamper with the record.

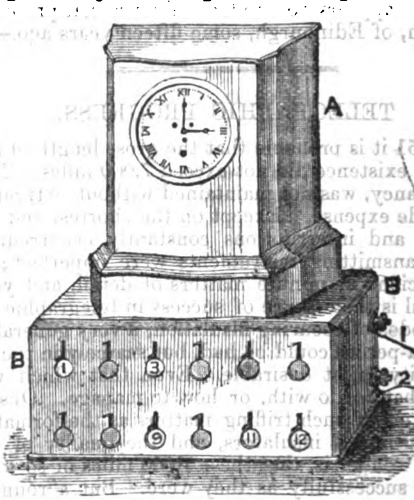

FIG. 1.

An apparatus is affixed to an ordinary clock, A, Fig. 1, so constructed as to communicate by means of electricity with certain small boxes, one of which is shown in Fig. 2, placed in different apartments or districts of a building requiring to be visited. The watchman is provided with a small key, by means of which he sets the sand-glasses each hour; by so doing he completes a circuit which would otherwise be broken by the ascent of the glass from an inclined to a vertical position, by the change in the position of

the centre of gravity, consequent on the fall of the entire quantity of sand into the lower glass.

Beneath the clock is placed a stand or base, B, Fig. 1, in the lower part of which are twelve apertures corresponding to the hours, marked on the dial above. In each of these is placed a small German silver slide, marked 1, 5, 10, &c., up to 12. The clock is placed in the master's private office, and the operation is as follows:—So long as the line is complete a label will drop into view as the hour-hand of the clock reaches each figure on the dial; but the circuit cannot be kept complete unless the hour-glasses, which are shut up in locked boxes, are turned regularly; thus the neglect of any one hour is registered by the non-descent of the corresponding label. It matters not if out of twenty glasses nineteen are in contact. The failure of the twentieth is inevitably registered.

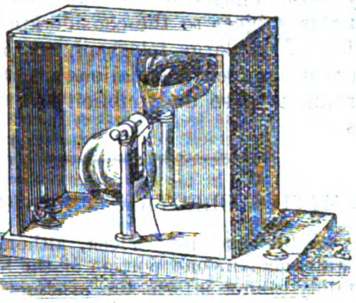

FIG. 2.

If the wires are tampered with, a bell is set ringing in the office until attention is attracted and the wires set right.

When desirable alarums can be rung at various hours, or at the same hour in many different rooms by the same clock. Thus, if need be, an entire village of factory operatives might be aroused betimes. It is evident that this electrical tell-tale is applicable to a vast number of purposes. It can be used on board ship; at railway-stations it can report the vigilance of outlying signal-men. In fire-engine stations, breweries, factories, mills, docks, or warehouses, it is likely to prove equally suitable.

[We are indebted to the *Mechanics' Magazine* for the above description, and to Mr. Sax for the blocks to illustrate the same; but we shall defer any expression of opinion concerning the utility of the instrument until we have had opportunity of examining it in operation. The idea of employing the hour-glass, in conjunction with electricity, for a registering tell-tale, is by no means novel; indeed the plan appears to us identical with that proposed by Mr. Alexander Bain, of Edinburgh, some fifteen years ago.—ED. *T. J.*]

TELEGRAPHIC PROGRESS.

IN the year 1851 it is probable that the gross length of all the telegraph lines in existence did not exceed 7,000 miles. The system, then in its infancy, was not maintained without extreme difficulty and considerable expense. Except on the shortest and most direct routes failures and interruptions constantly occurred. Both receiving and transmitting instruments were imperfect; as a rule, they were deficient in minute matters of detail, and yet the perfection of detail is the essence of success in telegraphic operations. Of the best modes of securing insulation, a very general ignorance existed. Gutta-percha could be had, but scarcely in the quantities, or of the quality, most desirable. Even that which we had we hardly knew what to do with, or how to manage. Obstacles were encountered even in such trifling matters as the formation of post lines, the procuring of insulators, and the quality of wire. The only matter of wonder is, that these 7,000 miles or so were worked as well and as successfully as they were. But a round dozen of years has elapsed since 1851, and each and all of these years have been marked by progress. In this matter of telegraphic communication by the aid of electricity the world has never retrograded a single step. There may have been delay, failure, mischance; but, nevertheless, we have gone onwards. The importance of the ends to be gained, the advantages to be derived, were too great to permit a moment's hesitation. Electrician has succeeded electrician, each taking up discovery where his fellow left off. And we thus find that that thing which first had existence in the minds of a few obscure labourers in the field of science now engrosses the attention, not alone of men or of companies, but of entire nations. Over 160,000 miles of telegraph lines now have existence, and it is not easy to find a corner of the earth from which we may not flash back intelligence to countries divided from us by thousands of miles. But great as this distance is, there is every probability that in a few years it will come to be regarded as comparatively insignificant. In spite of piteous wars and rumours of wars, nations in this matter have acted the better part; and so we find that the endeavour to facilitate communication by the establishment of new lines is heartily entered into by every civilized people without exception; while those which are not civilized either stand by and watch without opposing the operations of those who are, or, in their very ignorance, are content to submit to their dictation; and perhaps aid—certainly do not hinder—the gradual extension of the all-pervading wire.

A mere glance at the projects for inter-continental telegraph lines entertained at the present moment by the principal Governments is enough to prove how universal is the interest felt, how vast are the schemes proposed. The construction of the proposed line which, viâ Behring's Straits, will complete the circuit of the world, has lately been made the subject of earnest discussion in the New York Chamber of Commerce, and as the statements then put forward were elaborate, exact, and as authentic as anything well can be, we cannot do better, perhaps, than select from them the most remarkable facts.

It appears that Russia has undertaken the construction of a line of 6,000 miles from Moscow to the Pacific Ocean, at the mouth of the Amoor. Of this distance, 4,000 miles of line, from Moscow to Irkutsk, are in operation. Mr. P. M. Collins, of New York, has obtained a concession from the Emperor of 33 years to extend this line up to and across Behring's Straits, and from thence to the frontier of the British possessions—a distance in all of about 4,500 miles. The British Government have granted a similar privilege for the extension of the line down the Northern frontier of the United States, and an application for a like concession from the American Government has been laid before the Washington Congress. Thus will the telegraph systems of Europe and Asia be made one with that of America. The Chamber of Commerce unanimously resolved to memorialise the President and both Houses of Congress in favour of the undertaking. It is stated on good authority that the entire work of construction can be completed in three years. Behring's Straits are about 39 miles wide, and not more than 150 feet deep. The entire length of the completed line will be about 16,000 miles, and American telegraphists state that during the present year messages have been sent from Boston to San Francisco, a distance of 3,000 miles, in two minutes. Whether this has been a strictly exceptional effort or not does not appear. The fact of its being so would in no way detract from the value of the lesson taught.

The American Secretary, Mr. Seward, in the course of a report on Mr. Collins's scheme, recently laid before a Committee of the Senate, states that throughout that gentleman's negociations with the Russian and British Governments for leave to pass through their American possessions, he has been acting under the instructions of the American Government, and that his application to the Congress for a right of way across the public lands and the use of a national vessel is reasonable. Mr. Seward proceeds to say that the line which the Russian Government is constructing, or has undertaken to construct, from St. Petersburg to the mouth of the Amoor, is but a small part of the stupendous work which the Emperor has begun. His Imperial Majesty's design embraces also a telegraphic wire from the mouth of the Amoor, over the islands of Sakhalin and Jerro to Jeddo; also, from the Amoor, along the bank of the Usuri, to Viadi Vostok, on the coast of Tartary, Viadi Vostok being selected by the Emperor for his naval station on the Pacific coast; also a wire from the Irkutsk telegraphic line, through the vast territory of the Mongols, to Pekin; and American citizens in China are soliciting, with good prospect of success, permission from the Chinese Government to extend this line to Nankin, Shanghai, Amoy, and Canton. The Russian scheme comprises a wire from the main Continental-Russian line at Omsk, near the southern boundary of Asiatic Russia, through Mongolia, China, Turkestan, Bokhara, and Cabool, to meet the telegraphic system of India in the Punjaub, and connect it with Europe; and also a wire from Kazan on the main central Russian line, passing along the shore of the Caspian Sea to Teheran, and along the banks of the Euphrates to the Persian Gulf, there to be connected with the telegraphic system of India.

It will be seen from this that nearly every nation on the face of

the earth will be placed in direct communication with every other, if the Russian scheme is carried out, save Australia. Here, however, English enterprise takes the matter up. Already we are in communication with Bagdad, and ere long, it is probable that a line will be fully established between this town and Kurrachee, a distance of 1,410 miles. The Indian Government has consented to subsidise a line from Rangoon to Singapore, a distance of 1,090 nautical miles. In less than two years the Dutch Government will have fully established communication between Singapore and Batavia, and so, in connection with existing land lines, to the east end of Java. A glance at the map will show that the distance to be traversed between Australia and Asia presents no very alarming obstacles; and we may safely say that the day is not very distant when Melbourne will be in telegraphic communication with London, New York, or St. Petersburg. The establishment of an Atlantic cable between Cape Clear and Cape Race is only wanting to complete, at this moment, a telegraphic circuit round the world between 42° and 65° north latitude, and no man living can say how soon this line may be duplicated or tripled.—*Mechanics' Magazine.*

REPORT OF THE ASTRONOMER-ROYAL TO THE BOARD OF VISITORS OF THE ROYAL OBSERVATORY, GREENWICH.*

WE have to thank the Astronomer-Royal for a copy of his important and valuable Report. Amongst our subscribers there are many who will approve of a portion of our columns being devoted to the diffusion of such knowledge as the Report contains, especially that part which relates to electric and magnetic phenomena.

It has been my rule, in framing my Reports to the Board of Visitors for several years past, to adapt them to periods bounded at the beginning and at the end either by the beginning or by the middle of a lunation. The Report which I have the honour now to place before the Board applies to the period of twelve and a-half lunations, from May 17, 1863, to May 20, 1864.

I. Buildings and Grounds.—Only one change has been made in the astronomical buildings. It had long been remarked that the ventilation of the south dome (in which the altazimuth is mounted) was insufficient. I have therefore opened two windows into the room, one on the south and one on the east side. The south window is not often used, and is in fact at the present time blocked by a shutter; but the east window is almost perpetually open, partly by understood regulation and partly because the external thermometer is fixed without it; and the temperature of the room is now in an excellent state.

The north dome (formerly called the east dome or north-east dome) does not exclude the rain so perfectly as it ought. Instructions have been given to the proper workmen for its examination, and it may possibly be made water-tight by the time of the meeting of the Board.

Two piers have been built in the front court for the support of instruments which I expect Mr. Otto Struve to bring, to be used in observations connected with the Great Arc of Parallel. It was necessary to dig to the depth of 12 feet, to obtain a satisfactory foundation for the piers. A portable observatory is to be erected over them in some part of the approaching summer.

In a very heavy squall which occurred in the gale of December 2 of last year, the stay of the lofty iron pillar outside of the Park rails, which carried our telegraph-wires, gave way, and the pillar and the whole system of wires fell. By permission of the Department of Her Majesty's parks and public buildings, I was enabled to select a new position within the park, and thus, to attach the wires to a much shorter wooden mast. On the last day of the year, communication was again made perfect.

An important alteration has been made in the Magnetic Observatory. For several years past, various plans have been under consideration for preventing large changes of temperature in the room which contains the magnetic instruments. At length, I determined to excavate a subterraneous room or cellar under the original room. The work was begun in the last week of January, and in all important points it is now finished. The ground was cut down on all sides in the plane of the inner surface of the former walls, and within this space a 9-inch wall was built all round, so that the transverse dimensions of the room are less by 18 inches than those of the former room. Bricks were selected which were almost free from magnetism. The room is illuminated when necessary by three well-windows, facing the south; these can be covered by yellow glass, or by wooden shutters, and can otherwise be blocked. It can be warmed by a gas-stove, and lighted by gas-lights. Ventilation is provided by a large copper pipe leading to the ventilating-cowl of the upper room (no longer required for the upper room), through which pipe the warm stove-pipe is led nearly to the top. Drainage is effected by a pump in the ground outside of the building, about 20 feet distant from the eastern arm of the building. The building has been somewhat delayed by the illness of the Superintendent of Works, and also by the circumstance that the walls dry slowly. The reading of the atmospheric dew-point, at this season, is sometimes higher than the mean temperature of the ground, which is the temperature of the walls. It seems probable that the stove will be required more frequently in summer than in winter. On the erections for carrying the instruments, I shall speak hereafter.

The map of the grounds and buildings has been engraved; it is accompanied by a description, with historic references, which might have been more complete if, at the time of writing, I had been possessed of the documents to which I shall soon allude. The whole is finished, but the circulation, with that of other parts of the Astronomical Volume, is delayed for a reason to be mentioned hereafter.

No steps, so far as I am aware, have been taken in the present year, for urging the proposal of a railway through Greenwich Park.

II. Moveable Property.—With the exception of auxiliaries to instruments, which will be treated under a special head, no changes of the least importance have been made in the property serving for the active work of the observatory. Its ornamental property has received a most valuable addition, in a bust of the highest merit, by Foley, of the Rev. R. Sheepshanks, many years a member of the Board of Visitors; presented by Miss Sheepshanks.

The Visitors are aware that, under the provisions of the Standard Act, an official copy of each of the two fundamental standards (that of length, and that of weight) is preserved in the Royal Observatory. In the late spring, some alarm was occasioned by the discovery that the Parliamentary Standard of the Pound Weight had become coated with an extraneous substance produced by the decomposition of the lining of the case in which it was preserved. The appearance was so grave that the Lords Commissioners of the Treasury decided immediately to follow the course prescribed by the Standard Act for cases of destruction or injury of the Parliamentary (National) Standard, namely, to compare it with the three parliamentary copies of which that at the Observatory is one. The comparison was made by Professor Miller of Cambridge. It is satisfactory to know that the National Standard was found to be entirely uninjured. It is also interesting to know that the Observatory copy contributed its share to the evidence on this point. The occurrence seems to prove the propriety of the arrangement legalised by the Standard Act, for restoration of the standard in case of loss or injury, namely that of comparison with certain official copies. It would have been a most laborious business to test the standard by reference to the weight of water, as was provided in the last preceding Standard Act.

III. Manuscripts.—The ancient manuscripts are preserved with the usual care; and the current and accumulating manuscripts are, in the first place, arranged and stitched together on a peculiar plan, which, after many years' experience, we have found to be very simple and satisfactory; and, in the next place, are bound as soon as the number of papers collected under each head requires it. The operations connected with this are generally entrusted to Mr. Carpenter. The manuscripts are properly catalogued.

On the day of writing this report, a packet of Bradley's MS.S., relating principally to adjustments of the Greenwich instruments, has been transferred by the Rev. H. O. Coxe, Librarian of the Bodleian Library, Oxford, to the Royal Observatory.

I adhere peremptorily to the rule of not permitting any original manuscript to be taken out of the Observatory except by my own hands, and to be kept under my own eye.

Lately, however, I have found the advantage of preserving duplicates which may be for a time lent from the Observatory. Several years ago (as was then notified to the Visitors), I was permitted, by the courtesy of the Vice-Chancellor of the University of Oxford, to make accurate transcripts of Bradley's original Greenwich Observations, then preserved in the Bodleian Library. More lately (as the Visitors have been informed), the originals themselves have been transferred by the Senate in Convocation to the Royal Observatory. The copy is therefore free for use; and at the present time the copy of the observations from 1748 to 1749 (hitherto not printed) is in the hands of Mr. Hugh Breen for the reduction of the observations (hitherto not reduced), and the copy of the observations from 1750 to 1762 is to be lent to Mr. Winnecke, for more complete reduction of the observations than was made by Bessel.

In my reports for some years past, I have alluded to the supposed loss of the Minutes of the Board of Visitors from 1784 to 1830. I now believe that there never was such a collection in a separate form. The Board of Visitors was, in fact, a Committee of the Council of the Royal Society, and its Minutes are, I believe, contained in the Minutes of the Council. The volume which I possess, extending from the institution of the Board to 1784, consists of leaves inserted in a guard-book. Having learned that detailed minutes connected with the Royal Observatory exist in the Minutes of the Council of the Royal Society, I solicited of the President and Council permission to have those minutes copied; and the passages bearing upon the Royal Observatory were selected and marked by the Assistant Secretary of the Society. My best thanks are due to the President and Council of the Royal Society, for the liberality and promptitude with which they acceded to my request. I am very glad to possess in the Royal Observatory a series of documents which illustrate so much (and in the latter part nearly the whole) of its official history.

IV. Library.—Some purchases are made by me, confined to the subjects which are followed in the active business of the Observatory; but the principle increase of books is derived from presents.

* Read at the Annual Visitation of the Royal Observatory, June 4, 1864.

Preparations are made for the new catalogue, but it is not yet begun. It is intended to adopt the method of moveable slips, now employed in the principal large libraries.

V. Astronomical Instruments.—The transit-circle is in perfect condition. The index-pieces, to which in my last report I alluded to as being suspiciously near to the micrometer-heads, have been filed, and the micrometers have been put in good order.

A trifling want of steadiness has been discovered in the object-glass of the north collimator, which may have produced some of the discordances that were attributed to instability of the ground. The fault has been corrected, but I am not yet able to say whether the discordances are removed.

A series of observations lately taken for determination of the astronomical flexure of the telescope has given a result of insensible amount of flexure. This differs from the results obtained in former years. The process is to be repeated; meantime, I may remark that, if the late deduction should be confirmed, I should attribute the difference to a difference in the firmness of fixation of the eye-end tube, which has once been taken off and replaced.

On November 16th of last year the instrument narrowly escaped serious injury from an accident. Shortly after the operation of raising the transit-circle (for comparison of the collimators and cleaning the pivots), but when no person was near, the plate-chain which carries the large western counter-poise broke. The counterpoise fell upon the pier, destroying the massive gun-metal wheels of the lifting machinery, but was prevented from falling further by the iron stay of the gas-burner flue. Had it forced this it would probably have destroyed the microscopes, and might have injured the building by its ultimate shock on the ground. On examination it was found that many of the individual plates of the plate-chain were broken through. I lost no time in requesting the assistance of Messrs. Ransomes to re-suspend the counterpoises from strong simple iron chains, and to prepare large pulley-wheels with grooves adapted to guide the links of the chains in their proper position. Subsequently iron box-sides have been mounted, for so inclosing each counterpoise that, if it should fall, it will not fall from the top of the pier.

The transit-clock (lately cleaned) is in good order. To enable us to use another clock by the chronographic method when the transit clock is temporarily dismounted, I have had seconds-contact-springs inserted in the North Dome Arnold. The chronograph is in general good order, but I contemplate altering the form of its water-resistance mechanism, to give it the same arrangement as that of the large equatoreal clockwork. The reflex zenith-tube is in good order.

The altazimuth is in good order. The pinion-axis of the moderately-slow motion in azimuth lately broke, at a point where a screw-hole had been drilled through it. It has been repaired in a safer form. Much of the brass of the azimuthal microscopes had become rotten, and has been replaced. A similar operation is to be performed shortly on the vertical-circle microscope.

The apparatus of all kinds for galvanic signals is in good order. The motor clock has been lately cleaned, with much attention to the maintaining mechanism, and to the galvanic-contact surfaces; ebonite has been substituted for ivory in some of the insulating parts, and in order to diminish the mechanical interference with the motion of the pendulum, two pairs of pendulum-contact springs have been removed, their circuits being completed by a multiple relay, which is worked by the springs that are left.

The Shuckburgh equatoreal is imperfect as regards its hour-circle microscopes, but in other respects is in good order. The Sheepshanks' equatoreal (lately separated and cleaned by Mr. Carpenter) is in perfect efficiency.

The south-east equatoreal has had no change since the last meeting of the Board; it is in a perfect working state. An eye-piece with reflection from the surface of glass, for viewing the sun, has been provided for it: a construction which is very useful, where the whole aperture of the object-glass is desired for good definition, and where the accompanying heat is great. The water-clock movement is most accurate; I propose to give it the last degree of exactness by the following arrangement. The arc of vibration of the conical pendulum will sometimes vary a little from variations in the height of the surface of the resisting water. To make the vibrations isochronous, the part which we have usually called the "spade-apparatus" requires to be loaded at the top so as to overtip a little. Some years ago I had computed the quantity necessary for perfect isochronism, and I propose soon to introduce the principle practically.

I have not had sufficient leisure to prepare for publication plans of the south-east equatoreal.

The prismatic spectrum apparatus has been altered in the manner described in the last report. Achromatic object-glasses are placed on both sides of the prism, so that each pencil of light through the prism consists of parallel rays; and breadth is given to the spectrum by a cylindrical lens. The spectral lines are seen straighter than before, and generally it is believed that their definition is improved.

Of the ancient instruments, the limbs of the iron quadrant and of the brass quadrant have been cleaned, and covered with a rather hard varnish, under the superintendence of Mr. Simms. The other old instruments have been cleaned under Mr. Simms' eye, and the results of the examination have been interesting. One old instrument has, since the year 1835 at least, borne the repute of being one of Flamsteed's. On carefully examining it we find that it is a perfect small equatoreal of the German form, with a steel polar axis, conical hole in the lower end for bearing on a conical pin, and brass ring near the upper end for bearing in a Y; above which are its telescope and declination circle on one side. The oldest equatorial with which I am acquainted is Flamsteed's equatorial sextant, of which we have an accurate drawing in a very rare engraving; its mounting was of the German form. From the style of workmanship, as well as the general form, and from the circumstance that all Flamsteed's instruments are reported to have been taken away from the Observatory, I am inclined to believe that this old equatoreal is of Halley's time. Besides the coarse graduation on a small circle, by which the position of its declination frame was registered, it has a better graduation by which the position of the telescope on the declination frame was registered, and by which small differences of declination could be measured. Halley's unsymmetrical transit is in fair order; we remark on it a delicate screw motion, which might alter the error of collimation before certain parts were firmly fixed together. Bradley's transit appears to us to have been well put together, and not to have been liable to the flexure which Mr. Pond attributed to it, and which I conceive to have arisen from an error of collimation, not then perfectly understood by Mr. Pond. There seems to have been in it a ghost-apparatus for determination of level-error. It was never strengthened by braces.

VI. Astronomical Observations.—By long tradition, which I trust will always be maintained in this Observatory, the first place in importance is ascribed to regular observation of the principal fixed stars, rather than of the small ones; to observations of the sun, including the annual determination of equinox and obliquity, as well as of the sun's place in its apparent orbit; to observations of ~~the known bodies of~~ the solar system; and to observations of the moon. Meridional observations only are employed for all determinations, except those of the moon's place; but for the moon (whose tables, containing many rapidly-changing inequalities, can scarcely be sufficiently compared with her observed places in the heavens, as liable to the interruptions, both systematic and irregular, to which meridional observations are exposed), extra meridional observations with the altazimuth are also used. It was mainly for observations of the moon that the Observatory was founded; at no other observatory has the moon been followed in the same way, through more than a century, at every hour of the night-transit; and at the present time, when the claims of different observations conflict, the preference is always given to the moon.

The stars observed on the meridian are principally of the following classes (the same as in 1863):—189 stars for clock-error; all stars not smaller than the fifth magnitude; circumpolar stars; stars in the Nautical Almanac lists conculminating with the moon or occulted by the moon; stars assisting in inquiries relating to proper motion or refraction, or serving as standards of reference for the motion of Sirius; a few supplemental to the Seven-Year Catalogue. Among these observations ought also to be included the zenith-distances of γ Draconis, determined with the reflex-zenith-tube at nearly every practicable opportunity. A list of the whole of Bradley's stars is in preparation for re-observation.

The sun, Mercury, and Venus are observed on the meridian on every week-day, when visible. The large superior planets are observed on week-days when they pass before 14h, or when they pass near the morning moon. The moon is observed on every day when she is visible on the meridian, without any exception.

For observations of the small planets a convention has been made with M. Le Verrier, founded on the following considerations:—No relief would be gained by dividing the observations of special planets among special observatories. The seasons at which it is particularly desired that this Observatory should be spared the labour of observing the small planets are the times when the observers are oppressed with the duty of observing the morning moon. These remarks sufficiently explain the motive for proposing to M. Le Verrier the following system, to which he has acceded with the utmost liberality. From new moon to full moon all the small planets visible to 13h are observed at the Royal Observatory of Greenwich. From full moon to new moon all are observed at the Imperial Observatory of Paris. All ephemerides, results of observations, &c., are communicated freely from each superintendent of observatory to the other. The relief gained in this way is very considerable, principally because I am not compelled to provide observers both for the early morning and for the late night, partly also because the hours of night observation of these bodies are made to cease at 13h. The corresponding diminution of computation, though not so great, is very sensible.

The number of meridional observations with the transit-circle from May 17, 1863, to May 20, 1864, is as follows:—

Transits (the two limbs being considered as two objects) ...	3,729
Pairs of observations of the collimators by the transit-circle.	304
Reflexion-observations of the transit-wires	295
Observations of collimator by collimator	61
Circle-observations of all kinds	3,999
Reflexion-observations of the zenith-distance-wire	309
Reflexion-observations of stars	260

(The two last classes of observations are included in that which precedes them.)

The observations of γ Draconis with the reflex-zenith-tube are:—

Pairs of observations (the instrument being reversed between)	64
Single observations	11

In taking the observations with the altazimuth the reading of the barometer has been corrected for the small error which was found to exist in it, and the thermometer has been read more frequently, and at smaller

interval from the observations. The numbers of observations with the altazimuth, in their various classes, are:—

Azimuths of moon and stars	672
Azimuths of the collimator	356
Zenith-distances of the moon	364
Zenith-distances of the collimator	356

The following is the number of complete altazimuth-observations of the moon when near conjunction with the sun. The time of the moon's meridian transit on the days of altazimuth-observation, will sufficiently define the distance of the moon from the sun:—

Between 21h. and 22h.	3
Between 22h. and 23h.	1
Between 23h. and 24h.	0
Between 0h. and 1h.	0
Between 1h. and 2h.	2
Between 2h. and 3h.	4

The whole number of days on which complete determinations of the moon's place have been obtained with both instruments is:—

With the altazimuth, 190, or 15·2 per lunation.
With the transit-circle, 111, or 8·9 per lunation.

The earthquake of October 5, 1863, 15h. 53m. was seen with the altazimuth by Mr. Ellis, who happened to be observing the collimator. The mark appeared to descend, to rise rather more, and to descend a little to its original position.

With the south-east equatoreal no observations of numerical character have been made. The solar reflecting eye-piece has occasionally been used for examination of the inequalities of light on the sun's surface, and the spectrum apparatus has been employed for view of spectra of some stars. A drawing of the nebula of orion (still in pencil) has been made with much care by Mr. Carpenter. No observations have been made with the double-image or wire micrometer.

The number of observed occultations of stars by the moon is 12, of which 7 were disappearances and 5 were reappearances. The number of phenomena of Jupiter's satellites observed is 11.

VII. Reduction of Astronomical Observations.—The following progress has been made in the various steps by which the right ascensions of objects observed with the transit-circle are inferred from the observations: Transits are corrected for instrumental errors, and reduced to the state of clock-time transits over the true meridian, as far as May 15; clock errors and clock rates are computed to May 14; apparent right ascensions of the object's centre are found to May 14; stars' corrections are computed as far as May 15 (except those not previously observed, whose constants are not yet prepared), and are actually applied to the apparent right ascensions as far as December 31, 1863; corrections for imperfect illumination of limbs to December 31, 1863; mean solar times are prepared to December 31, 1863. For inferring geocentric north polar distances from observations: True zenith distances corrected for instrumental flexure, zenith point, and refraction, are formed to May 12; stars' corrections (limited as above) are computed to February 16, and are applied as far as December 31, 1863; lunar parallaxes are computed and applied to April 12, other parallaxes are computed and applied to March 12; corrections for imperfect illumination of limbs are applied to December 31, 1863.

The different results of each star's mean right ascension, and for each star's north polar distance, are collected in what is usually called the "Ledger" form for the year 1863. The star catalogue for 1863 is completed; the number of stars is 765. The investigation for R — D is made for 1863, and gives a value nearly according (at the zenith distances at which the observations are most frequent) with that of the last years. The investigation for correction of colatitude for 1862 gives the smallest colatitude that we have yet obtained, namely, 38°.31′.21″·58. That for 1863, lately finished, gives 38°. 31′. 21″·79.

Right ascensions and north polar distances of sun, moon, and planets, deduced from observations, are compared with those computed from tables, to the end of 1863. The conversion of errors of R.A. and N.P.D. (taking the mean of groups) into errors of longitude and E.N.P.D., and other deductions from them, are completed for 1862, but are only commenced for 1863.

The observations with the reflex-zenith-tube are reduced to December 31, 1863.

The altazimuth observations are reduced, in different parts of the chain of calculation, to the following states:—Observed azimuths are corrected for instrumental errors and zero of azimuth, to April 25; observed zenith distances are corrected for zenith point and refraction, to April 25; tabular azimuths and zenith distances, to the same date; errors of moon's tabular R.A. and N.P.D., and errors of moon's tabular longitude and ecliptic N.P.D., to April 1.

The reduction of the equatoreal observations of 1862, to which allusion was made in the last report, and which was then unfinished, is now complete.

The occultations of stars by the moon are reduced to the end of 1862; no important step is yet made for those of 1863.

It appears from the transit-reductions that the personal equations of the observers have changed very little. Three observers, not often employed on transits, have changed, with reference to Mr. Dunkin, by + 0s·12, — 0s·09, and + 0s·08; but four assistants more frequently employed have changed by only 0s·00, — 0s·01, + 0s·01, and — 0s·01.

The azimuthal error of the transit-circle continues to make its annual oscillation; the error being always very small in the month of September. The azimuthal zero of the altazimuth is still liable to irregular changes.

I am not yet able to exhibit such a comparison of moon's N.P.D. derived from altazimuth observations, with moon's N.P.D. obtained by the use of the transit-circle, as will authorise me to say whether the small discordance which appeared to exist in former years is removed by the alteration of the altazimuth dome, and the improved practice of observation of its barometer and thermometer.

The seven-year catalogue of 2021 stars from observations in the years 1854-1860, which was mentioned in the last report as nearly finished, has been completed.

I request the attention of the Visitors to a white globe, on which we have laid down all the stars observed from 1836 to 1860.

VIII. Printing and Distribution of Astronomical Observations.—The astronomical printing for 1862 is somewhat increased by the addition of the appendixes containing the redetermination of the longitude of Valencia and the seven-year catalogue. And the magnetical and meteorological printing, for reasons which will shortly be mentioned, is unusually large. I have therefore thought it desirable, for 1862, to separate the printing into two parts. The astronomical volume for 1862 has been printed some time since, but to prevent the confusion which might arise from distributing this, the first part, alone, I have thought it expedient to wait for the completion of the second, or magnetical and meteorological part. Separate copies of the seven-year catalogue have been received, but I have not had leisure to attend to their distribution.

Nearly the whole of the manuscript of the principal sections of the observational part for 1863 (transits and zenith distances with transit-circle, azimuths and zenith distances with altazimuth, and comparison of altazimuth determinations with tables), is in the printer's hands. The following is the number of sheets already printed:—Transits, 4; circle observations, 2; azimuths with altazimuth, 1; zenith distances with altazimuth, 1; comparisons of observed and tabular places for altazimuth, 1.

In the section containing the results of observations of the small planets I propose to incorporate with our own the results of the observations made at the Paris Observatory, under the convention which I have described. This combination is approved by M. Le Verrier.

The whole impression of the volumes for 1861 and 1862 is 350 copies. The volume for 1861 has been distributed, and that for 1862 is to be distributed, to the same extent as that for 1860.

(To be continued.)

SILVER'S INDIA-RUBBER WORKS AND TELEGRAPH CABLE COMPANY (LIMITED).

An extraordinary general meeting of the shareholders of the above company was held on Thursday last, at the London Tavern, Bishopsgate-street, for the purpose of confirming the resolutions passed at an extraordinary general meeting of the shareholders on the 30th June last, and which were as follows:—

1st. The increase of the capital of the company by the issue of new shares; such aggregate increase to be of such amount, not exceeding £500,000, and to be divided into shares of £50 each, or of such respective amount, and to be allotted in such manner as the company in meeting shall direct, or, if no direction be given, as the directors shall think expedient.

2nd. The change of the name of the company from "Silver's India-rubber Works and Telegraph Cable Company (Limited)," to "The India-rubber and Gutta-percha and Telegraph Works Company (Limited)," according to the power given by the 13th section of "The Companies' Act, 1862."

3rd. The substitution of the following regulation in lieu of the regulation now contained in Article 44 of the Articles of Association of the company:— "All capital and all other moneys of the company not immediately applicable for any payment to be made by the company may be deposited or invested by the directors in or upon such personal or other securities or investments, other than stock or shares of the company, as the directors from time to time think proper."

Dr. Beattie having been voted to the chair, the secretary proceeded to read the notice calling the meeting. The minutes of the former meeting were then read and confirmed, after which the chairman remarked that that extraordinary meeting had been simply called to confirm the resolutions which had been agreed to at the last meeting, and which had just been read to them. He would therefore move that the resolutions agreed to at the previous meeting be now confirmed, which, having been put to the meeting, was carried unanimously.

The CHAIRMAN said that it might be satisfactory to them to be informed that the managing directors had just returned from the works in France and Belgium, and had given favourable accounts of the state of affairs there to the Board, who had been sitting that morning. Some little alterations and organisation will be required there, and there was a prospect of a very satisfactory businesss being carried on abroad as well as in England.

Thanks to the chairman and directors for the way in which they were conducting the affairs of the company having been moved by Mr. Reep, and carried unanimously, the chairman briefly acknowledged the compliment, and the proceedings terminated.

COMMUNICATION BETWEEN PASSENGERS AND RAILWAY GUARDS.

WE quote the following letters which have appeared in the daily papers upon the above important subject, with the hope of awakening the attention of telegraph engineers and electricians thereto, believing that it is to electricity that we must look forward for the most efficient means of effecting the object in view :—

Sir,—The time has now arrived when the subject of a proper means of communication, in time of danger, between railway passengers and the guards and drivers of railway trains, is likely to be forced on the consideration of railway companies; and as various plans are likely at the present time to meet with mature consideration, I beg leave, through the columns of your influential paper, to launch a suggestion which appears to possess the merit of being simple, practicable, and effective. The means are these :—I propose that there shall be affixed permanently, above the roof of each carriage, a small flag, furled, and a lamp, unlighted. By day the flag may be unfurled by mechanical means, at the will of a passenger. By night the lamps may be illuminated by similar means. Thus a particular carriage may be at once indicated to the guard of the train, whose duty it shall become to attend to these signals. To provide against wanton or unnecessary use of these signals the railway companies should have power to inflict penalty by fine or imprisonment.—I am, sir, yours, &c.,

Putney, July 12. A. J. P.

Sir,—At a time when the necessity of a mode of communication between the passengers of a railway train and the guard, or engine-driver, will be most earnestly canvassed, I trust you will be kind enough to publish, in your very valuable journal, the following simple plan for ensuring such a desirable communication. I would suggest that a tin tube be placed along the top inside of each carriage, and to each end of the tube projecting out of the carriage be fixed tubes of india-rubber, with junction screws, for the purpose of forming a connecting link from carriage to carriage throughout the train from the guard to the engine-driver. Suspended from the tube in each compartment of all the carriages would be an india-rubber tube, with a mouthpiece, to answer the purpose of a blowpipe. Now, if a whistle be fixed at each end of the tube thus formed, viz., one in the guard's box, and another close to the engine-driver, I think that a vigorous puff from any compartment would start the whistles, and thus give the desired alarm. It would not take long to connect the tubes before starting, not longer than trimming and lighting the lamps; but what is a little trouble to the feeling of security that would be felt by the passengers ?—I am, sir, yours, &c.,

July 12. J. B.

Sir,—To prevent the repetition of tragedies in railway carriages, it seems to me that a few simple expedients would be all that would be necessary. 1st. Carry out your suggestion of a communication between the compartments of each carriage, so that passengers in one might see what is going on in the next. 2nd. Add to every guard's van a glass projection of about eight inches on each side, so that the guard could command a view of the doors of all the carriages, and that, by waving a pocket-handkerchief, his attention would be attracted at once. This for the day. Then, by suspending the lamp of each carriage by a rod or pulley, and allowing the passengers the expedient of raising it in case of necessity, the guard—who can always see along the top of the carriages—would notice it, and it would be an easy danger-signal at night.—I am, sir, yours, &c., A. V.

July 12.

Sir,—As I am perfectly aware that any means of safety to the travelling community would receive the greatest attention through your valuable publication, I venture to suggest a plan at once cheap and effective, which can be applied to any existing carriages.

On the outside of each compartment let there be a brilliant red disc, which can be raised by a cord within the reach of any passenger; at night a lamp may be placed, the light of which would be intercepted by either of the discs when raised. The guard who sits at the end of the tender should be in a direct line with the disc, and by the aid of a strong handrail could walk by the foot board on the six foot side to the compartment so signalled.

I am, sir, yours respectfully,

Bath, July 12. PHILIP BRAHAM.

Sir,—Criminal deeds being not unfrequently perpetrated in railway carriages, perhaps you will allow space in your widely-read journal for the following hint to railway companies :—

Bells, or other means of communication with the guards, are obviously surrounded by many difficulties, and even if practicable cannot always be depended on.

Let, then, the companies at once set to work, and have a pane of glass placed in the division between each compartment of a carriage. If it should so happen that only three persons travel in one carriage, and two should be in one compartment of it, let the third be compelled, if they do not all ride together, to sit in the next compartment, so that there might be a means of seeing if anything wrong was going on, and thus affording means of identification, &c. Public safety will be a sufficient compensation for any curiosity that might be exhibited by any one.

The adoption of this plan, I am convinced, will give confidence to every [illegible]

Yours, &c., AN OCCASIONAL TRAVELLER.

July 12.

Sir,—I was but yesterday proposing to a railway official a somewhat similar plan for communication between passengers and guard to that advocated by your correspondent "A. J. P.," with the exception that I suggested the raising of a small metal disc on the top of the carriage instead of a flag, and that the lowering of this disc, after being once raised, should only be effected by means under the control of the guard on or in the carriage bearing the signal. One very important desideratum, however, in connection with any method of signalling, is to provide for the guard free and comparatively easy access to the carriage on which he may observe a signal raised. It appears to me that this could be most satisfactorily arranged by lengthening the wooden step boards at the sides of the carriages, so that when coupled up the two boards of adjacent carriages should meet on either side, care being taken to arrange for the "play" distance of the buffers; and further, that a running rod, to serve as a handrail, should be substituted for the existing single handles at the sides of the carriages; the step-board being also raised from its present almost useless position, about three feet below the floor of the carriage, to the level of the iron entrance-step. Now-a-days the van has usually a raised glass look-out, through which the guard can see over the whole train. Were the metal discs I suggest also made reflectors, a light thrown from the guard's van along the top of the train would show any of them raised by night quite as well as by day. Nothing but a simple arrangement for raising these discs, and one which could be easily used from either side of the inside of the carriage, is further required. Tubes and whistles will not do. Something which can be caught at and used in a moment by a weak or struggling person must form an integral part of any adopted plan.

July 13. I am, sir, yours, &c., R. W. H.

REVIEW.

LA TÉLÉGRAPHIE ELECTRIQUE : son Histoire Précise, Anecdotique, et Pittoresque, et ses Applications en France, en Angleterre, aux Etats-Unis, en Belgique, en Hollande, en Suisse, en Espagne, en Italie, en Turquie, en Russie, en Perse, dans l'Inde, en Cochin Chine, etc., etc. Suivi d'un Guide de l'Expéditeur de Dépêches. Par PHILIPPE DAURIAC.

A little volume of 116 pages, part of which is composed of tables showing the rates of charge for messages sent over the wires of different countries, has been recently published in Paris under the above ambitious title. A little more than two pages comprises all the information that the author can discover of sufficient interest in English telegraphy. America is dealt with in about the same space, and a few lines suffice for the other countries enumerated in the title, with the exception of the telegraphs in the French settlement in Cochin China, consisting of about 300 miles of line, and 12 stations at Saigon, Bien-Hoa, Cholen, Baria, Mytho, Thuan-keou, Tran-Bang, Long-Than, Thu-Yen-Moi, Tay-Ninh, Goden and Tan-an, to which is devoted about the same space as that apportioned to all the English and American telegraphs. In alluding to various projects for crossing the Atlantic by a submarine cable, M. Dauriac first takes in hand the direct route between Valentia and Newfoundland, for the success of which, however, he does not offer up any prayers, as he considers that it will give England the monopoly of telegraphic communication between the two continents, and that she will probably abuse such a privilege.

We cannot discover any description of novel telegraphic appliances, or proposals for new instruments or lines throughout the work, the extensive title of which will no doubt disappoint others as well as ourselves; but our readers will at least have the advantage of being forewarned as to the degree of enjoyment which they may anticipate from a perusal of M. Dauriac's pretentious treatise. It has been said that to write well one must write fast, and Goldsmith said that "everybody wrote better because he wrote faster than I"; but now-a-days the speed appears to have got up to a rate that requires checking. There is too much of this sort of book-making, and "La Télégraphie Electrique" is about the most glaring instance we have met with of a novice venturing to deal with a large and difficult subject, of which he has scarcely acquired even a glimmering of knowledge.

A FIRE ALARM TELEGRAPH.—A fire alarm police and water telegraph is about to be erected by Messrs. J. & F. Kennard, in Chicago, America, at a cost of 70,000 dollars. According to the specification a building for a central office is to be procured, and fitted up with all the necessary instruments, scattered all over the city, with 103 signal boxes. There will be 8 electro-magnetic bell-ringing machines, with 13 engine-house gongs with hammer and magnetic escapement to alarm the firemen the instant intelligence of a conflagration is flashed over the wires to the central office. In the police department of the telegraph there will be 6 indicating dial instruments with call bells, this will be one machine for each police station head-quarters and the central alarm office, so that information in regard to fires will be given from any police station. The superintendent will also be in a position to communicate at any instant with any or all of the station-houses. Each of the city reservoirs will be connected by telegraph with the waterworks, so that the condition of the water, whether high or low, can at all times be ascertained. A gong will also be placed in the waterworks and all alarms of fire will be given the same as at the engine-houses. This will allow a full head to be turned on the instant an alarm is given.

CORRESPONDENCE.

INDIA RUBBER COVERED CABLES.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—That something is still wanting to insure the permancy of caoutchouc covered cables doubtless all will admit, and the same may be said of every project, design, and enterprize under the sun. Here we all stand on common ground. The real point at issue is, what is that "something?" Doctors will disagree: It is this, that, or t' other, according to the stand point occupied, or the prejudice, or the interest, or the what-not of the eminent self-constituted jurists, but seldom the right thing. One of the "somethings" required to accomplish this desired object is to abjure the use of tar utterly on the serving of hemp that is put on the core. Don't say this is arrant dogmatism, and purely suppositious; it is founded on actual experience, and practical chemists will confirm the statement. Substitute tarred hemp with hemp simply steeped in water, and wrap it on wet, and you at once insure permanency of the core, because you bring nothing into contact therewith that can possibly do injury to the rubber—rather you add a preservative. How can we reasonably be surprised at the failure of India rubber covered wires when brought into immediate contact with such villainous stuff as tar! Do you know what enters into the composition of Stockholm tar? or, supposing you do, can you guarantee its entire freedom from extraneous matter? There is the point. Assuming it to be inocuous in its effect upon rubber when purely constituted, it would even then be dangerous to use, from the fact that its purity cannot be depended upon; the slightest mixture of any grease in it would destroy any cable, but grease or no grease, tar is destructive to India rubber.

At the time when the twenty miles of cable, referred to in your last week's number, was being tested at Mr. Henley's works, Mr. Hay, the Admiralty chemist, being present, remarked to Sir W. Brooke that no caoutchouc covered wires could be expected to last for any great length of time when covered with tarred yarn *in a moist state:* and further remarked, that had the yarn, after being steeped in tar, been dried before applied to the core, or had it been steeped in water only, it would have proved a preservative.*

It is notorious that in this instance the yarn was brought seething hot from the tar pot, and immediately applied, and this it was that led to the remark of the gentleman above referred to. Unquestionably this was twenty miles of good core spoiled by the rigorous martyrdom it underwent from this and other causes after it left the works of the manufacturers. This was partly foreseen by these gentlemen, and hence it was that they declined to be responsible for the core after it had passed the prescribed ordeal of Mr. Reid's pressure test, &c., and was thence handed over to other parties to do the sheathing; and here it may with propriety be stated that the makers of this core would not be responsible for the permanence of any cable that was not manufactured throughout under their own supervision and in conformity with the specification of their patent.

The object of this letter is to set ourselves right with the public. No one has any right to attribute the deterioration of an India-rubber cable to the unsuitableness of that material, unless it can be demonstrated that it is unsuitable after the cable has been manufactured entire by those who are thoroughly acquainted with the nature of the gum; it is equally disingenuous and unjustifiable to bring into disrepute the manufacture of any one who makes a core and who declines to be responsible for it when handed over to some one else to finish, when the parties who are chargeable with such an unworkmanlike procedure know that such responsibility is declined upon principle, and because the makers know that the subsequent handling it must undergo can do it no good but rather harm, and specially in this instance, seeing we have always entered our protest against the prevailing mode of manufacturing the outer part of submarine cables. We guarantee the permanency of the cables we manufacture entire, and fortunately we are in a position to produce the highest testimonials confirmatory of this; but we guarantee no cable *that passes into other hands to finish,* and if the twenty miles in question be in the condition described, the entire blame, liability, and responsibility is repudiated by the

MANUFACTURERS OF THE CORE.

[We insert the above communication with much pleasure, as the subject is one of the greatest importance with respect to the future of submarine telegraphy.—ED. T. J.]

* See also Professor Miller's Report Blue Book, page 340. In a conversation we had with Dr. Hoffman, on the 11th instant, that gentleman expressed himself strongly upon the matter, and condemned the application of Stockholm tar in the manufacture of cables, unless it could be prevented coming in contact with the insulation.

THE MALTA AND ALEXANDRIA CABLE.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—Your correspondent, "One of the Public," has called attention to an item of £680 included in the estimates of the current year. The sum in question is the amount of the salary and travelling expenses of a superintendent appointed on behalf of the Lords of Her Majesty's Treasury. The appointment at the time it was made was the subject of much animadversion; the fortunate individual, a junior clerk in the Board of Trade, wholly unacquainted with the science of telegraphy, being selected. As far as I have been able to discover, the only recommendation was that of possessing the same patronymic as the President of the Board of Trade. Perhaps that it is owing to this fact that so much mysterious secrecy hangs over the operation of this line.

July 13, 1864. G. TWEEDALE.

COMMUNICATION BETWEEN PASSENGERS AND RAILWAY GUARDS.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—The frightful murder perpetrated on the North London Railway on Saturday evening, the 9th inst., has again revived the question as to the necessity of having a means of communication between passengers and the guards and drivers of railway trains. Several lamentable occurrences have happened, which might have been frustrated had there existed such means of communication. Numerous plans have been suggested and patented during the last twenty years, mostly by the application of electricity for the purpose, but every effort to induce railway directors and their officials to adopt any of the means suggested, have hitherto failed. Had there been a means of communication between the compartment in which the present murder was committed, even the knowledge of its existence might have had a deterring effect on the assassin; and in the instances of assault upon women which have taken place, the possibility of giving an instant alarm would prove a most effectual protection. A most efficient electrical apparatus could be fitted to each carriage at a very small expense. No difficulty whatever would be experienced in effecting the continuity of the electric wire by the addition to or detachment of any number of carriages from the train. I believe that in every other country in the world the means of communication between the passengers and the officers of the train exist except in England. I am, sir, your obedient servant,

July 14, 1864. J. LAWRENCE.

TELEGRAPHIC NEWS.

SPEZZIA AND CORSICA CABLE.—The submarine telegraph has been successfully laid between Spezzia and Corsica, and is now in excellent working order. The steamer Fanny Lambert has been engaged in this useful operation.

THE TELEGRAPH IN FRANCE.—An agreement has been entered into by the Governments of Italy and France, by which telegraphic messages may be sent to and from any portion of the two kingdoms at the rate of four francs for the simple message of twenty words.

LONDON DISTRICT TELEGRAPH COMPANY (LIMITED).—The above Company have issued a notice that the next half-yearly ordinary general meeting of the shareholders of the Company will be held at their offices, 90, Cannon-street, London, on Thursday, the 4th day of August next, at 2 o'clock, P.M. precisely; and the business to be transacted at such meeting will be the reception and consideration of the accounts, balance sheet, and report of the Directors, and other general business of the Company.

ANGLO-INDIAN TELEGRAPH.—Between Fao and Dewanigon, and over the incomplete portion of the intervening ground, mounted messengers will be despatched, twice a week at first, and daily as soon as relays of horses can be provided. Thus messages will pass between Europe and India in five days, until the opening of the Persian line completes the chain of telegraph. Colonel Stewart may fairly be congratulated on the success which has hitherto attended his exertions. We hear from Bussorah, up to the 2nd of May, news to the effect that the messengers will be despatched on the morning of each Tuesday and Saturday, and an extra messenger will constantly be in readiness to take on any message of unusual importance. Until regular districts are settled, these men must take a circuitous route, but the messages will be delivered in Bagdad in about five days. Arrangements have been made at Bagdad, and as soon as the Constantinople line is repaired, service messages and heads of general intelligence from Europe may be expected twice a week in Bombay. As soon as the country is quiet, relays of horses will be provided, and messages will then pass between Bussorah and Bagdad every day, occupying about two days in transit instead of five days.

NON-TARRED SUBMARINE CABLE.—Messrs. Wells & Hall have, within the past few days, delivered several miles of india-rubber covered wires for Government telegraphs, a few particulars of which we append, because the length of core evinces a proficiency of workmanship of a very satisfactory and reassuring character, and augurs well for the future of submarine telegraphy, if the same care is exercised and perfection attained in the manufacture of the outward part of the cable as is now attainable in what is technically termed the "core." The wire in question consists of a No. 18 (diam ·043) tinned copper, insulated to a total diam of ·25 inches; weight of copper per mile, 30lbs.; weight of insulator per mile, 60lbs. The resistance of the insulating medium for one mile, tested in water at a temperature of 60 degs. Fahrenheit is 4,750,000 Siemens' units; and the resistance of the conductor, 54 S. 26. It will be obvious from this that the insulation tests, both static and dynamic, are of a very high character in comparison with results obtained in other materials. No tar is to be applied to this core, on account of its well-known deteriorating effects when brought into contact with the rubber. The durability of this material is now satisfactorily established, if engineers will avoid the use of tar, and be more cautious that the protecting sheathing does not belie its character, by introducing an element or elements of destruction..—(*Communicated.*)

THE GREAT EASTERN.—Intelligence was received at Sheerness on Wednesday morning that the Great Eastern steamship had passed Dover at 4.50 a.m. on her passage from Liverpool, which place she left at noon on Saturday, the 9th instant, for Sheerness. It is intended to moor her at Sheerness for the purpose of taking on board the Atlantic telegraph cable, now in course of manufacture at the works of the Telegraph Construction and Maintenance Company (Limited) (late Glass, Elliot, & Co.), East Greenwich. Mr. R. A. Glass, managing director of the company, and Mr. Shuter, the secretary, arrived in Sheerness in the course of the day, to await the arrival of the Great Eastern, and to complete arrangements for her permanent mooring at Sheerness. The Great Eastern has been placed under the command of Captain Birch, an experienced commander of steam vessels, assisted by Mr. W. C. Moore, a Trinity pilot of considerable experience, who accompanies the vessel from Liverpool, Mr. Daniel Gooch, one of the directors of the Telegraph Construction and Maintenance Company, and also a director of the Great Ship Company, together with Messrs. Canning and Clifford, the engineers who are to be intrusted with the laying of the cable, are also on board, with a view of watching the working of the machinery. Three powerful steam-tugs awaited the arrival of the vessel at the Great Nore. At four o'clock in the afternoon of the same day the Great Eastern arrived at the Nore, and shortly afterwards bore up to Sheerness Harbour, where she was saluted by the Formidable flag-ship and other Government vessels lying off the dockyard, the compliment being promptly returned. The monster vessel appeared in excellent trim, working but a portion of her screw machinery, and she was towed into harbour by four steam vessels, two on either side. The pier, the whole frontage of the dockyard, and every available spot commanding a view of the noble vessel, was crowded by thousands of spectators, who greeted her by repeated cheers, and the excitement of the scene was enhanced by the arrival at the pier, at the same time, of the Orcad steam vessel, with the directors and shareholders of the Woolwich Steam Packet Company, returning from their annual trip to the Medway. The volunteer band on board this vessel and the whole of the passengers warmly joined in the manifestations of applause which prevailed. At six o'clock the big ship was moored in the harbour, where she will remain until she has shipped the whole of the Atlantic telegraph cable. Captain Superintendent C. Wise, A.D.C., of the Sheerness dockyard, placed at the disposal of the contractors the Locust steam-tug, Master Reuben Harvey, to assist in bringing the Great Eastern to her permanent moorings in the Medway of Sheerness, where ample space is afforded the vessel for swinging with every tide. The Admiralty has also placed at the disposal of the company the sailing ships Venus and Iris, for the purpose of conveying the cable from East Greenwich, where it will be manufactured. Both these vessels will be immediately fitted with large iron water-tight tanks, into which the cable will be coiled as completed. It will then be conveyed to Sheerness to be reshipped on board the Great Eastern, which will also be fitted with watertight tanks to receive it, ready for submersion. The fitting of the tanks on board these vessels and the shipment of the cable on board the Great Eastern will not be completed till about June, 1865, when it is intended to commence the operation of laying the Atlantic telegraph cable.

THE ANGLO-AUSTRALIAN AND CHINA TELEGRAPH COMPANY (LIMITED).—The prospectus of this company is in private circulation, and will be shortly published. In the first instance it is intended to issue capital for the first section from India (Rangoon) to Singapore, a distance of 1,200 nautical, or 1,400 statute miles. This will require a capital of £450,000, in 22,500 shares of £20 each. The board is composed of fifteen highly respectable names, and comprises representatives of the Peninsular and Oriental Steam Company, and other weighty interests. The trade to be accommodated by this section represents about £75,000,000 per annum, and stress is justly laid upon the importance of the proposed submarine telegraph to the shipping interest, the more especially as the stations will be near the coasts and Straits of Sunda and Malacca, along which lies the great highway for vessels to the East. Considering the special interest attaching to this undertaking, both in a political and commercial sense, it may be useful if we reproduce the following description of its objects as furnished to us by the promoters. We will merely add that the section in question can be completed in eighteen months. The Anglo-Australian and China Telegraph Company, which has been constituted to carry out a complete system of telegraphs between India, Singapore, China, Java, and Australia, is about to carry out the India-Singapore telegraph as its first work. To effect this object the company will lay a telegraph cable between Rangoon and Singapore, with intermediate stations at King Island and Penang. The length of this line is one hundred miles less than that of the Malta and Alexandria submarine telegraph, which has now been at work for nearly three years, and the cable can be laid in a depth not exceeding fifty fathoms, thus securing the permanence of the work, and enabling any necessary repairs to be executed with speed and certainty. The official returns of the receipts on the Malta and Alexandria telegraph show that the earnings of that line have steadily and rapidly increased since its first opening in 1861. Thus the receipts in the last quarter in each year have uniformly proved nearly double those of the first quarter in the same year. In the last quarter of 1863 the Malta and Alexandria telegraph was earning at the rate of £86,240 per annum, which amounts to 20 per cent. gross upon the cost of the line (£436,000), and say 16 per cent. nett. There is every reason to believe that the India-Singapore line will be still more profitable. The India-Singapore telegraph will place the whole of India in direct telegraphic communication with the Straits of Malacca and with Singapore, and will reduce the time for communicating with Batavia, the Straits of Sunda, Hong Kong, and Shanghai, to about the time occupied by the mail steamers between Singapore and those several points. The enormous amount of shipping engaged in the trade of India and of Europe with Singapore, Java, and China all passes through the Straits of Malacca or of Sunda, and will extensively use the India-Singapore telegraph for communications with owners, consigners, and consignees of cargo, insurers, &c. A submarine line is eminently adapted to accommodate shipping in consequence of the proximity of the stations to the coast. There is also a very large coasting trade between India and Singapore carried on in native vessels, which will largely use the telegraph. The advantages of the proposed line by no means depend upon the completion or maintenance of telegraphic communication between Great Britain and India, the trade between India, Singapore, and China, and the local trade of the Straits will in any case be directly accommodated by the proposed telegraph.—*Malta Observer.*

MISCELLANEA.

WHAT NEXT?—Telegraph wires are now being erected to cross over the summit of Mount Washington, to connect all the public-houses in that region with each other and with Boston.—*New York Observer.*

THE METAL LITHIUM.—This metal is the lightest known solid. It floats in naphtha, and yet can be drawn into a fine wire. It is harder than potassium, but softer than lead. It does not inflame in water, like sodium, but does so when dropped into fuming nitric acid, the most active oxydizing agent known.

CALCULATION.—A flash of lightning on the earth would be visible on the moon in a second and a quarter; on the sun in eight minutes; on Jupiter (when furthest from us) in twenty-five minutes; on Uranus in two hours; on Neptune in four hours and a quarter; on the Vega, of the first magnitude, in 4,000 years; yet such stars are visible through the telescope!

UNIT OF FORCE OF CURRENT.—Every conductor of electricity, however good, opposes some resistance to its propagation, and many researches have been made to determine the laws of the transfer through conducting media. Galvanic electricity tends to diffuse itself through the whole capacity of a conductor, and consequently the resistance to conduction is in proportion inversely to the transverse section of a conductor.

INDURATION OF IRON.—The iron work of the new bridge at Blackfriars is to be indurated by a process patented by Messrs. Morewood & Co., and is alike important from the great cost which will be incurred, and the testing of a rather abstruse chemical formula for the preservation of iron from oxidation and decay. The process is as follows:—The iron is to be thoroughly cleaned, and heated to the requisite temperature in a furnace planned by the inventors. When this temperature is attained, it is to be plunged into a bath of prussiate of potash and chloride of potassium, in a molten state, so that when the iron is withdrawn it may easily part with the surplus of the aforesaid chemicals, which should run off like oil. The iron is then to be dipped into boiling water, containing a certain proportion of cyanide of potassium; from thence it is removed to a bath for a final washing, and set up on end to dry. All the processes are to be carried on under cover, and before exposure to the atmosphere the iron is to be coated with an asphaltum paint twice, at given intervals; and again it is to receive two coats after fixing. Of course, all the necessary planing, drilling, and fitting, is to be done preparatory to the indurating. The time the iron is to remain in the bath will vary from one to five minutes, according to the weight of the metal to be operated upon. The elaborate character of the process to which the contractor is rigidly bound, will account for the large sum to be expended in carrying out this part of the work; £4 per ton is allowed to the contractor for the induration and painting; Messrs. Morewood will receive from the contractors 5s. per ton as their royalty, which it is estimated will be £1,000. Thus £16,000 is to be spent in this effort to prevent oxidation, no greater proof of which, in its damaging results, can be offered than the case of the cleaning of the oxide (or rust) from the Menai Bridge, from which has lately been removed above forty tons of oxide of iron.

Telegraph Lines in Belgium.—On the 1st of January, 1864, the Government telegraph had been extended over a distance of 2,647 kilometres. In this line the number of conductors employed varies from 1 to 15; the total length of copper wire in use exceeding 6,238 kilometres.

Military Telegraph in the United States.—This important branch of the United States war department was considerably extended in the year 1863. The Government now maintain 5,326 miles of telegraph, of which 1,755 miles (aerial and submarine cable) were constructed last year. The number of war messages, mostly characterised by extreme urgency, transmitted by this line amounted to 1,200,000, or about 3,000 per day, each telegram containing from 10 to 1,000 words.—*Annales Télégraphiques.*

The Most Useful Metal.—"That iron should have been one of the last metals to come into general use," says Mr. Smiles, "is partly accounted for by the circumstance that, though it is one of the most generally diffused of minerals, it never presents itself in a natural state except in meteorites; and that to recognise its ores and then to separate the metal from its matrix demands the exercise of no small amount of observation and invention. The effectual reduction of the ore requires an intense heat maintained by artificial methods, such as furnaces and blowing apparatus. But it is principally in combination with other substances that iron is so valuable when compared with other metals. Thus, when combined with carbon in various proportions, substances are produced so different, but each so valuable, that they might almost be regarded in the light of distinct metals—such, for instance, as cast iron and cast and bar steel; the various qualities of iron enabling it to be used for purposes so opposite as a steel pen and a railroad, the needle of a mariner's compass and a six hundred-pounder gun, a surgeon's lancet and a steam-engine, the hair-spring of a watch and an iron ship, a pair of scissors and a steam-hammer, a lady's ear-rings and a tubular bridge."

The Cause of Diamagnetism.—Professor Maas, of Namur, in a communication made to the Royal Academy of Sciences of Belgium, expresses his opinion that water is the determining cause of the diamagnetism of certain organised substances. He states that Faraday, in his work on magnetism, has ranged elderpith and ivory among diamagnetic bodies. After having observed the diamagnetism of a small prism of elder, he was surprised to find it changed to para-magnetism a short time afterwards. In order to ascertain the cause, he cut from a long cylinder of oldish elder-pith two prisms, using a knife electrotyped with copper. One of these prisms was left exposed to the air, the other was enclosed in a flask containing some drops of distilled water. The first was found to be powerfully axial-magnetic, the other as powerfully equatorial. M. Maas hence concludes that the water made the latter diamagnetic. Several slices of ivory cut in different directions from an old piece equally surprised him, since none placed itself across the axis of the magnet; one placed itself axially; another made a very open angle with the same axis. A third example was a small cylinder composed of starch, gum arabic, and water. Freshly prepared it placed itself transversely, but when spontaneously dried it became para-magnetic. "Hence," says M. Maas, "we may be permitted to suppose that many natural organic substances owe their diamagnetic property to the interposition of liquids, of which water forms the larger proportion." The apparatus employed in the experiment was a Faraday's electro-magnet, modified by Becquerel and constructed by Secretan.

Atmospheric Investigation.—Mr. Glaisher, in a recent communication to the morning papers, makes the following statement:—There was one peculiarity in this ascent, as I before stated, distinct from all others, and that was the frequent freedom from any revolution of the balloon; at times for ten or fifteen minutes certain objects kept in the same azimuth: this enabled me to take twenty different sets of vibrations of a horizontal magnet with as much accuracy as I can take them on the earth. The results of these experiments showed clearly that the magnet vibrated in a longer time than on the earth. This result is very valuable in our present state of magnetical knowledge. There were in the car, in addition to Mr. Coxwell and myself, Mr. Woodroffe, Royal Horse Guards, Mr. W. F. Ingelow, Mr. E. Atkinson, Mr. J. Atkinson, Mr. F. W. Ellis, and Mr. Collins. At the height of 1,600 feet the number of pulsations in one minute of the several gentlemen were as follows:—Mr. Woodrooffe, 120; Mr. Ingelow, 108; Mr. E. Atkinson, 78; Mr. Coxwell, 84; Mr. Collins, 108; and myself, 104. The number of respirations in one minute were:—Mr. Woodroffe, 19; Mr. Ingelow, 18; Mr. E. Atkinson, 17; Mr. Collins, 11; Mr. Coxwell, 15; and myself, 18½. Mr. Collins repeated the experiment with the same result, and spoke very decidedly about his correctness. The ratio of respirations to pulsations were therefore as follows:—Mr. Woodroffe, 1 to 6; Mr. Ingelow, 1 to 6; Mr. E. Atkinson, 1 to 5; Mr. Collins, 1 to 10; Mr. Coxwell, 1 to 5½; and myself, 1 to 5½. At midnight, at Brookland, Mr. Coxwell's pulsations were in one minute 90, Mr. Collins's 94, and mine 88; our respirations were 18, 15, and 17½ respectively; therefore the ratio of respirations to pulsations were—Mr. Coxwell, 1 to 5; Mr. Collins, 1 to 6; and mine, 1 to 5. The ratio of my ordinary respirations to my ordinary pulsations is as 1 to 4½, so that the removal of even that small amount of atmospheric pressure, as experienced on this occasion, disturbed the system, but with undoubted advantage, as enjoying the pure air of the mountains without any fatigue, increasing the ordinary pulsation by 20 to 30 in one minute, increasing also the number of respirations, but not in the same degree. This disturbance lessened, but had not ceased 2½ hours after we were again on the ground. On the following morning my pulsations numbered 76 and respiration 17 in one minute, and had therefore assumed their normal action.

PATENTS.

APPLICATIONS FOR LETTERS PATENT.

1720. R. A. Brooman, improvements in batteries and in electric printing telegraphs.—A communication.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

1538. W. J. Pughsley, improvements in obtaining sulphuric acid from the refuse "pickle" used in tin plate works, and also from sulphate of iron or green copperas.

1545. J. Forbes, improvements in the means of, and apparatus for, manufacturing sulphate of ammonia and sulphuric acid.

1565. J. D. Adams, improvements in electrical communicators.—A communication.

PATENTS SEALED.

169. F. J. Ritchie, improvements in the application of magneto-electricity to the propelling and controlling of sympathetic clocks.

PATENTS ON WHICH THE STAMP DUTY OF ONE HUNDRED POUNDS HAS BEEN PAID, AND DATES OF THEIR PRODUCTION FOR CERTIFICATE.

1873. F. C. Hills, improvements in the manufacture of sulphuric acid.—Dated 6th July, 1857.

1947. W. E. Newton, improvements in the manufacture or reduction of platinum.—A communication.

Electric and International Dramatic Club.—A report of the benefit performance of the 14th instant will appear in our next.

W. J. M., Richmond.—The information you require will be found in the Parliamentary Return of Miscellaneous Statistics. In the *Telegraphic Journal* for 2nd January you will find a statement of the number of public messages sent by telegraph during the years 1859, 1860, and 1861; beyond this date no Government statistics of the telegraph have appeared to our knowledge.

As information respecting Improvements, Extension of Lines, and Progress of New Undertakings will at all times be most acceptable, we hope that our readers will kindly render us assistance, by furnishing us with brief notices of events and occurrences in connection with electrical and scientific progress.

Communications intended for publication must be authenticated by the names and addresses of the writers; not necessarily for insertion.

Letters relating to Advertisements are to be addressed to the Publishers. All other letters and communications to be addressed to the Editor of the *Telegraphic Journal*, 4 & 5, Suffolk-lane, Cannon-street, London, E.C.

The *Telegraphic Journal* can be had of Messrs. Smith & Co., Strand; Messrs. Dawson & Co., Cannon-street, E.C.; Messrs. Kent & Co., Paternoster-row, London. Messrs. Heywood & Co., Manchester; at the various railway stations; and of all news-agents, &c., &c.; or it can be supplied, if preferred, direct from the Office on the following terms:—

Quarterly, 4*s.* 4*d.* | Half-yearly, 8*s.* 8*d.* | Yearly, 17*s.* 4*d.*

TO ADVERTISERS.

The *Telegraphic Journal* is the most effective medium for inventors, patentees, contractors, manufacturers of insulating materials and electrical apparatus to submit their various specialities to the consideration of secretaries and managers of telegraph or railway companies, and other persons engaged in electrical and telegraphic pursuits.

Clerks, assistants, manipulators, and instrument makers, seeking employment, &c., will find the *Telegraphic Journal* a ready means of making known their requirements.

Advertisements must be delivered to ensure insertion before Seven O'Clock on Thursday evening in each week. The charges for Advertisements are—

FORCE AND FORM.

CONTRIBUTED BY B. M.

III.

No doubt it will be said, that the facts are against me: that attraction does take place in straight lines: that gravity is in straight lines: that Ampére's laws of the attraction and repulsion of parallel electric currents prove, that attraction and repulsion are in straight lines: as also his laws of angular currents. Well, I will not say, all the worse for the facts; because I have a profound reverence for a fact. At least I may be permitted to say, let us see whether this thing be so or not.

As to whether gravity does take place in straight lines, I would not like to attempt to say anything at all; because I know just nothing about it: and moreover I do not know anybody who knows anything about it; so we will let that stand till we have some facts to speculate upon. As to Ampére's laws—well, I do know somewhat about them, both at first and second-hand, and also of his theory of magnetism. What I would desire to be permitted to do, would be to study Ampére by the light of Ampére. Here are his laws:—When two parallel metallic wires are traversed simultaneously by an electrical current, the wires are either attracted towards or repelled from each other, according to the relative directions of the two currents. When they move in contrary directions, as shown by the arrows in Fig. 1, there is mutual repulsion, and when in the same direction as in Fig. 2, there is mutual attraction.

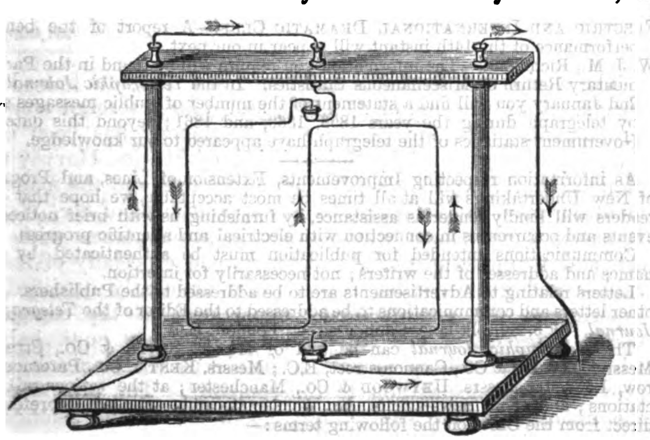

FIG. 1.

As to Ampére's mathematical laws, which govern the force of the attraction and repulsion, I have nothing to do here; for they are equally applicable whether the attraction and repulsion takes place in straight lines or spirals. Before we examine these laws of attraction and repulsion of electric currents let us first state, as clearly as we can, Ampére's electro-dynamic theory of magnetism.

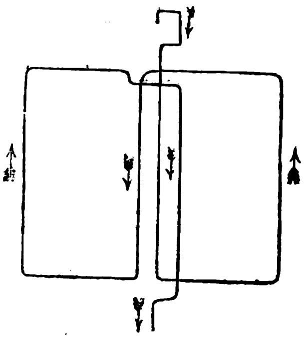

FIG. 2.

Having observed the mutual action of *solenoids* and permanent magnets, and also of electric currents generally, he was led to deny the existence of a magnetic fluid, and to consider all magnetic phenomena as the visible effects of electric currents perpetually circulating round the ultimate particles of which the magnet is formed, each magnetic atom being considered not only as a perfect magnet, but also as a perpetual electric circuit, somewhat similar to a solenoid, which is a spiral of wire with one end brought straight back through the centre. Every magnet is composed of these little magnets, their spheres of power coalescing to form one great magnetic sphere, the electric currents flowing round at right angles to the axis of attraction, or magnetic axis. Now, reducing this to its ultimate, we shall get one spiral current, or single curve of the solenoid, one side of which will act as a north pole, and the other side as a south pole, therefore in any two, the like sides will repel, and the unlike attract, which is actually found to be the fact in spiral currents. Now, what have we in Fig. 1, where the current in the fixed support moves in an opposite direction to what it does in the moveable rectangles? As all curved lines are made up of an infinite number of straight lines, there are segments of every imaginable curve in these straight lines, consequently they will act in precisely the same way as single spirals, and in these two, one is inverted, or turned round, so that we have the current flowing in the opposite direction, that is, like side is opposed to like side, which is equivalent in a magnet to north being opposed to north, or south to south; consequently repulsion must ensue.

In like manner, if the moveable rectangle in Fig. 2 be substituted for the rectangle in Fig. 1, the unlike sides of the current will be opposite; therefore, unlike magnetic polarities, will be induced; and consequent attraction must ensue, according to Ampére's own theory, for his theory affirms, that currents of electricity excite magnetic attraction at right angles to themselves. Certainly he denies altogether the existence of any magnetic fluid, and, as far as I can understand, he considers magnetism but a manifestation of electricity. Still, to develope magnetism a spiral current of electricity is necessary according to his theory of magnets. As we proceed we shall be able to show that magnetism and electricity are at least two distinct forces. What we wish to show here is, that according to Ampére's theory, if magnetism be induced at all, it is in spiral currents of force; therefore, in the cases shown the attraction and repulsion takes place in spirals, and not in straight lines.

Let us now see if his angular currents are governed by the same law.

Two rectilinear currents, which diverge from, or converge to a common point, mutually attract. If one converge, and the other diverge mutual repulsion ensues.

Let a b and c d be two currents crossing at the point e; there will be attraction between a e and c e, and between d e and b e, but there will be repulsion between a e and d e, as also between c e and b e.

Now, if the dotted lines, s n, represent the axes of magnetic

force which will be induced by the currents, *a b* and *c d*, it will be clear why the currents, *a e*, *c e*, and *b e*, *d e*, attract each other, and why *a e*, *d e*, and *c e*, *b e*, repel each other; for between the former two pairs the unlike poles are opposite, and in the latter two pairs the like poles are opposite.

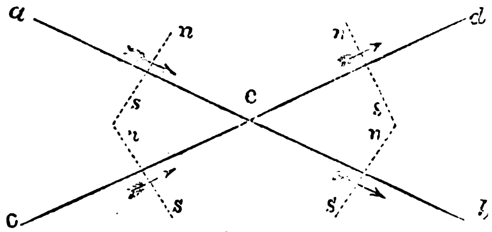

FIG. 3.

Moreover, it is clear from the following experiment (which experiment is well known to everybody), that simple currents do not attract or repel. Let the dotted lines represent a magnetic needle suspended over the current; it will place itself at right angles to the current, with its equator exactly over the current, if it be freely suspended, and if it be suspended with one of its poles just over the current, that pole will not be attracted by the current; but will pass over it, till the equator of the needle be brought in a line with the current, clearly showing, that the needle is not attracted by the current, but is simply striving to place itself parallel to the axis of magnetic force, which is induced by the current: in fact, conducting itself as if there was an invisible needle placed under it at right angles to the current.

So much, then, for Ampére's laws of the attraction and repulsion of parallel and angular currents of electricity. It appears from a little further generalization that they are simply cases of his one great law of magnetic induction, and that the currents themselves do not attract or repel each other at all, but it is the magnetism induced by them, and that force of necessity acts in spirals.

Mechanically speaking, what form of matter can be conceived, which will have a drawing or repelling power when force is exerted in it, in an onward, or backward direction, but a spiral? Is not the screw the universal application of this form? Nor can any other be supposed, as far as I can see. When speaking of mechanical motion, there is one curious fact that I will state, which is shown by the compound gyroscope, a fact well known to all those, who are practically acquainted with mechanical motions. If the inner ring of the gyroscope be put in motion, then the outer ring will commence to move in the opposite direction: but I have seen this more clearly exhibited in a lathe. In turning a piece of metal in a lathe, whose right hand centre was loose in the socket, the fixing screw having become slack, the centre began to turn round in an opposite direction to that in which the metal was being turned. What I would particularly take note of in this is, that motion induces motion in the same plane, but in an opposite direction. This, by the way, we shall have to refer to, when treating of induction: I do not mean of electricity only, but of force generally.

THE INDIA-RUBBER AND GUTTA-PERCHA AND TELEGRAPH WORKS COMPANY, LIMITED.

THIS project, lately brought into the money-market as "Silver's India-Rubber Works and Telegraph Company, Limited," with a capital of £500,000, is now in a very fair condition. The purpose of the Company was to purchase the extensive india-rubber and telegraph business of the Messrs. Silver, carried on in Bishopsgate-street, London, and at Silvertown, Essex. So soon as the required capital had been subscribed, however, it transpired that another company (supported by gentlemen of capital and influence) was in course of formation, having for its object the introduction of improvements in the manufacture of india-rubber and gutta-percha goods. This, it was thought, might possibly lead to unnecessary competition. It was accordingly adjudged wise to endeavour to effect an union of interests; and, as favourable opportunity offered for amalgamating several continental establishments engaged in the gutta and rubber trades, negotiations were entered into which rendered it necessary to increase the capital to £1,000,000 sterling. The sanction of the shareholders to these proceedings of the directors has been obtained, and a very powerful organization, under able superintendence, has been developed for the employment of the new gum, balata, in the manufactures so successfully carried on for many years by Messrs. Silver. The above arrangements have not been effected without great exertion on the part of the managing directors, and it is due to the indefatigable labours of the Messrs. H. A. Silver and J. W. Willans, that so desirable a fusion of interests has been brought about.

Some idea of the promising character of this undertaking may be derived from the statement made by Dr. Beattie, at the late meeting of the shareholders:—"Within the last three months the business of the firm of Messrs. Silver & Co. has increased 20 per cent. over that of the corresponding period of last year; whilst in one department, since May, 1863, the returns have been trebled." It appears that of the original capital, only £250,000 worth of shares has been issued. Of the £500,000 additional capital proposed to be raised, in order to meet the probable extension of trade, it is determined to allot £250,000, of which the French and Belgian interests have the option of taking £100,000, and the new gutta-percha company, £150,000, of which they have pledged themselves to take £100,000, leaving £50,000 for disposal among their friends. Accordingly there is abundant opportunity for further investments, should the directors determine to raise the whole of the capital, as will be seen by the following figures:—

Issue of Original Capital	£250,000	
Concession to the French and Belgian interests	100,000	
Apportioned to the New Gutta-Percha Company	150,000	
		£500,000
Unappropriated		500,000
		£1,000,000

The works and freeholds in France and Belgium have been purchased for the sum of £65,000, and a large foreign trade is anticipated. The directorate of the company has been considerably strengthened by the addition of Messrs. Harvey and Henderson, the well-known Borneo merchants, and the management has been supplemented by the appointment of Mr. Walter Hancock, a gentlemen whose practical acquaintance with the arts and manufactures of this country, and especially of india-rubber and gutta-percha, renders him eminently qualified to superintend the manufacturing department of the company. Great expectations are entertained of the new gum, balata, which, in the hands of so able a chemist as Mr. Hancock, may prove a great acquisition to the company. The prospects of the undertaking are exceedingly good, and as the science of electricity, in its application to telegraphy, is becoming more precise, there is every probability of a large business being done in the manufacture of submarine cables. A comparative monopoly in this trade appeared imminent awhile ago, but we have reason to believe that the India-Rubber and Gutta-Percha and Telegraph Works Company will be able to effect important improvements in subaqueous telegraphy, and render the business less exclusive in character.

INSULATION.—The Gutta Percha Company represents that the Dover and Calais cable exhibits no deterioration after a submersion of thirteen years.

ON THE MEASUREMENT OF ELECTRICAL TENSION.

BY LATIMER CLARK, M.I.C.E., F.G.S.

I.

IN conducting some experiments for the British Government on the phenomena which present themselves in connection with the manufacture and working of submarine telegraph cables, it became necessary to employ certain new methods of measuring electrical tension, some of which are herein described. The term *tension* is here intended to signify electromotive force, or potential, or the difference of state which subsists between the two coatings of a charged Leyden jar, or the poles of a battery, and which causes a current to flow between them whenever a wire is connected from one to the other; many instruments have been invented for measuring the higher tensions, such as the electrometers of Milner, Coulomb, Snow Harris, &c., most of which depend on the attraction or repulsion of electrified bodies, but none has been described for directly measuring lower tensions, such as those of a voltaic battery or a single galvanic couple, although these tensions are so constantly used in practice.

The tension of a single cell of Daniell's battery forms a very convenient unit and one often referred to, and the instrument about to be described is designed for subdividing this unit of tension into any number of equal parts. It consists of a board of any convenient length, having a fine platinum wire stretched upon it and attached at each end to blocks of metal, which are provided with convenient screws for the attachment of wires; the space between the blocks is graduated into one hundred equal divisions. A constant difference of tension, equal to one unit is maintained between the two blocks, and for this purpose a single cell of Daniell's battery is connected by wires to the terminal blocks, so as to form a circuit through the platinum wire, and a galvanometer is interposed in the circuit to indicate when any current is passing. In addition to this circuit a second battery of two or more large cells is connected between the two terminals, with a rheostat included in their circuit to enable the operator to regulate the quantity of electricity furnished by the battery; these cells are connected in the opposite direction to the single cell, and when joined up they overpower it, sending a current through the platinum wire in an opposite direction to that of the single cell, and also a reverse current through the cell itself; by lengthening the wire of the rheostat the force of this current is now reduced until it no longer overpowers the single cell, but just balances it, the needle standing at zero, in which condition a slight alteration of the rheostat in one direction or the other, causes either the one or the other battery to preponderate, and enables the operator to maintain the single cell perfectly inactive, as indicated by the galvanometer; in this condition the difference of tension between the two ends of the platinum wire is exactly equal to one unit, and, by a well-known law, the tensions at different points along the wire vary directly as their distances from the extremities. The instrument is used in the following manner:—Let us suppose that it is desired to measure the electromotive force of a couple of metals having less energy than the Daniell's cell, as for example iron and zinc; these are arranged as a galvanic couple, the size being immaterial, and an extremely sensitive galvanometer is connected with them, the zinc side being connected to the same block as the zinc plate of the single cell, and the other end remaining free; if now the free end be placed in contact with the other block, the feeble tension of the zinc and iron couple will be overpowered by the Daniell's cell, but if connected to the platinum wire near the zinc block, the couple will become active, sending its own current through the platina wire, and in either case its galvanometer will be deflected to one side or the other; by now sliding the free end along the platina wire, an intermediate point is readily found at which the tensions are exactly balanced, the needle of the galvanometer resting at zero, and the degrees in hundredths of the unit are then read off upon the graduated scale. It is obvious that the difference of tension between the two blocks may be made greater or less than one cell, all the degrees on the scale becoming magnified or diminished in proportion; the accuracy of the instrument has been verified in this manner up to a tension of 200 cells Daniell.* In the same manner the value of each degree may be increased tenfold by employing fifteen or twenty cells for the larger battery and connecting the standard cell at the tenth division on the scale. The platina wire may advantageously be doubled to and fro on the board to increase its length; it of course has its temperature affected by the passage of the current, but the increase being uniform it does not affect the accuracy of the measurement.

Another kind of measurement much used in the investigations above referred to, consisted in charging a length of submarine telegraph cable inductively, by connecting it with the source of electricity, and estimating the degree of tension by observing the amount of electricity discharged, when the cable was placed in connection with the earth, the discharge being measured by the deflection of the suspended needle of a delicate galvanometer. It is found with most galvanometers that within very considerable limits the arc of deflection varies nearly in proportion to the quantity of electricity discharged from the cable, and consequently nearly in proportion to the tension with which it has been charged; the error of each instrument is readily ascertained and tabulated by charging successively, one, two, four, &c., similar lengths of cable, or by charging a given length of cable with varying numbers of cells, and observing the deflection when the charge is suddenly allowed to return through the galvanometer to the earth; if the instrument be wound with very fine wire, a single mile of cable will measure deflections; with a less sensitive instrument, or a lower tension a greater length of cable is requisite;† the needle should be long so as to vibrate slowly; as it is known to what point the needle will arrive, it is easy, by the use of a magnifying glass, to read with great accuracy, and the mean of many observations should be taken. The needle must be rendered motionless before each observation, which is readily effected by approaching the poles of a very feebly magnetised steel rod to the centre of the needle while oscillating, increasing its distance each oscillation.

As the discharges from a submarine cable are very constant and little affected by temperature or other causes, this form of measurement admits of considerable accuracy; like the former arrangement, it is well calculated for measuring the electromotive force of various combinations of metals, or of batteries up to several hundred cells. A length of cable connected with an elevated wire or flame would slowly acquire the same tension as the atmosphere at that spot, and enable much more feeble tensions to be measured than can be detected by the electroscope. A cable connected with a long insulated telegraph wire would assume internally the same tension as the earth at the spot where the wire was connected with the ground, and during aurora borealis would accurately show the difference of tension between the two stations.

Its most interesting application has, however, been to the determination of the tension at the different parts of a simple galvanic couple, and the result has been as unexpected as it is instructive. Ever since the discovery of the galvanic battery philosophers have held divided opinions as to its nature and mode of action, and many of the greatest names in science have at different times ranged themselves either on the side of the "contact theory" or the "chemical theory." The object the

* See Government Report on Submarine Cables, p. 295, or a pamphlet entitled, "Experimental Investigation of the Laws which affect the Propagation of the Electric Current in Submarine Cables," by the author. London, 1861: Eyre & Spottiswoode.

† See Report, or pamphlet, above-mentioned.

author sought to attain was to measure the tension at the zinc plate, at the copper plate, and at all points of the intervening solution; for, although it is well known that the tension of the one plate is above that of the other, it is not known whether the tension increases gradually in the liquid from one plate to the other, or whether half the increase takes place at the surface of each plate, or whether all the increase occurs abruptly at one plate or the other. The experiments made have, however, shown that all the change takes place at the surface of the zinc plates, and have proved, moreover, that the presence of a negative metal is not at all necessary to the formation of the galvanic current, and that its presence or absence has no influence on the result. The contact of a single oxidizable metal with water is all that is requisite for the formation of the current. The following experiments will illustrate this:—A length of fifty or a hundred miles of telegraph wire or submarine cable is immersed in water, and one end insulated; the other end is connected to a very sensitive galvanometer wound with fine wire. A piece of copper is laid on the moist earth, and connection is made with it by a wire of any kind of metal leading from the galvanometer; of course no effect is visible; the copper being removed, a piece of zinc is substituted, and connection made as before; at the first contact a discharge is seen to pass out of the cable through the zinc to the earth, more or less powerful, according to the length of cable employed. No effect is produced at the second or subsequent contacts, even if a fresh piece of zinc be employed; but if a piece of copper be again substituted, a charge is seen to enter through the copper into the cable, and its amount is found to be exactly equal to that which left it at the first contact with the zinc. If the cable be now connected with an ordinary galvanic pair of zinc and copper, the amount of charge entering or leaving the cable is found to be precisely the same as when the metals were used separately and singly. Again, if the cable, after being connected with platinum, be successively connected to copper, iron, and zinc, three separate weak discharges will be seen to leave it, or if it be connected at once to zinc, a strong discharge will leave it, and the sum of the three weak discharges is exactly equal to that of the strong one.

The rationale of these experiments appears to be this: each metal when in contact with water becomes oxidised, at the same time giving off electricity to the water, and lowering its own tension thereby; as soon as a certain specific difference of tension is attained, either by the fall of that of the metal or the rise of that of the liquid, all action ceases, and a fragment of zinc under this condition remains as unalterable as gold; the degree of inequality necessary is different with each metal, varying apparently according to its affinity for oxygen. If while a piece of zinc is in this negative condition a plate of copper or platinum be placed in contact with it, and also with the water or earth, a channel will be formed by which the deficient electricity in the zinc can be perpetually restored, the oxidation again goes on, and a current will consequently continue to pass from the water through the copper to the zinc until the whole of it is dissolved; if the plate of copper be in connection with the zinc through a wire, it will still serve to restore continually the electrical equilibrium, even although the plates be a thousand miles asunder. Any inoxydisable conducting matter will serve this purpose as well as copper, such, for example, as carbon; or an inert conducting liquid may be used, and we then have the well-known galvanic arrangement of a single metal with two dissimilar liquids. Although we have only been considering negative effects, it will be easily seen how the same action produces positive electricity; if a plate of zinc be connected with the earth by a wire, and a piece of moistened cloth be placed upon it, the zinc oxidises, giving its electricity to the liquid, and raising its tension until the specific difference is attained, and the action ceases; if a piece of platina be laid on the moistened cloth it acquires the same tension as the liquid, and forms a convenient collector of the positive electricity; and it may, in like manner, have a second piece of zinc and cloth laid upon it, each series raising the tension of the one above it one specific degree above its own tension, and the whole constituting the ordinary voltaic pile.

THE TELEGRAPHIC INVENTIONS OF PROFESSOR HUGHES.

ONE of the most recent amongst the gracious acts of the Emperor of the French has been the decoration of Mr. Hughes, Professor of Physics at the University of New York, with the Cross of the Legion of Honour. We subjoin a few details on the system and apparatus of the learned Professor. Professor Hughes' system consists of the production of any species of letter by means of a single current, whereas other essays at telegraphic printing rendered the use of a large number of wires, or a multiple operation for the transmission of each character, absolutely necessary. The French Government, perceiving at once the value of this bold idea, desired to possess the exclusive rights of the inventor, and caused several of Professor Hughes' apparatus to be placed on its lines. They soon, however, discovered that the invention, in its pecuniary condition, was not practicable, and Professor Hughes was requested to endeavour more fully to develope his discovery. With the valuable aid of the celebrated maker, M. Froment, Professor Hughes so successfully altered his instruments that he was enabled to transmit signs of punctuation and figures, which he had not previously done. Since that time the invention of Professor Hughes has been used with the greatest success by the Administration. It is in operation between Paris, Havre, Lille, Bordeaux, Lyons, and Marseilles, forty words being printed in a minute at an average rate of fifty messages per hour. The services of Professor Hughes are not confined to the above alone. The learned Professor, after careful study, has established the laws by which the magnetic fluid distributes itself in the electro-magnets, and the rules to be observed to obtain the maximum force. He has shown that every quantity of iron added to an electro-magnet above that which corresponds to this maximum diminishes its energy in the most perceptible manner. This discovery will, it is very clear, considerably diminish the cost of the batteries now used by telegraphic companies; in fact, Professor Hughes has succeeded in working a circuit of 1,000 kilometres with a battery of two cells, the one formed of copper, the other of zinc, divided by a little water. The Professor's inventions will shortly form a special subject in a pamphlet for the information of the scientific world and the makers of instruments.—*Le Moniteur Universel du Soir*.

THEORY OF THE CONSTITUTION OF THE SUN.—The following is a *resumé* of a long memoir on this subject by M. Emile Gautier, in the *Bibliothique Universelle*, in which he gives an account of the principal observations and theories that have hitherto been published:—1. The sun is a liquid incandescent globe, constituted of elements similar to those which enter into the composition of the earth, and probably into that of the planetary system. It exists in a state analagous to the phase of liquidity through which the earth has passed, according to the opinion generally entertained by geologists. The high temperature by which its liquidity is maintained considerably dilutes its volume, and explains the feeble relative density of the globe in a state of fusion. 2. An atmosphere envelopes the liquid mass, and encloses in suspension vapours or emanations of all kinds, so that its lower strata ought to be comparatively heavier than those of the terrestrial atmosphere. As the rotatory motion of the central globe cannot be supposed to be transmitted to its gaseous envelope, so far as its most elevated limits with the same angular velocity, the solar atmosphere is probably susceptible of exercising on the liquid surface an action analogous to friction. 3. The emanations or metallic vapours surrounding the sun, and impregnated with dust, smoke, or lava, form around it a layer of variable thickness, and present total eclipses, the appearance of red borders, and protuberances. The solar dark spots are partial solidification of the surface, due either to cooling or to chemical action, remitting momentarily into aggregates salts, or oxides, which have issued from the mass in fusion, and float on its surface. 5. The faculæ (bright spots) are the result of the appearance on the sun of very brilliant substances endowed with great radiating power 6. The acceleration observed in the rotatory movement of the spots situated near the solar equator is the result of the exterior action of the atmospheric pressure on the liquid surface, combined with that of the interior layers of the mass in fusion. Accidental irregularities may proceed from the disturbance of the chemical and physical equilibrium of the various materials composing the mass.

MALTA AND ALEXANDRIA TELEGRAPH.

THE following is an Account of the Number of Messages forwarded each way by Line of Telegraph between Malta and Alexandria, printed by command of the House of Commons, distinguishing Government and Private Messages, and the Local from the Through Traffic; and of the Gross Receipts from all Sources, from the Opening of the Line, 1st November, 1861, to 31st December, 1863:—

DATES.	Number of Government Messages.	Number of Local Messages.			Number of "Through" Messages.			TOTAL Number of Messages.	Gross Receipts of the Line.

CAPTAIN AND MR. SPRYE'S PROPOSED OVERLAND TELEGRAPH TO CHINA ACROSS EASTERN PEGU FROM RANGOON.*

THE extension of the Indian telegraph wires now existing in Eastern Pegu *by land* to Hong-Kong, &c., if not directly beneficial to the Government of India in communicating with that more eastern part of the world, must prove most advantageous to all the merchants of India having connection with the trade of Eastern China and Japan; and certainly such an extension of the Pegu wires must very greatly increase the usefulness and income of the telegraph lines of India generally, since all messages by it between Europe, India, and China will pass both ways, from one point or another, through the Indian wires.

Passing by for the present the completion of the Indo-European line down the Persian Gulf, we will observe that on the arrival of the English mail steamers at Galle from Suez, long bulletins of news are now telegraphed to Calcutta, 1,380 miles, in three hours at the utmost. From Calcutta such messages can be passed on by the existing wires to Shwaygyeen, in Eastern Pegu, in less than two-thirds of that time, the distance being under 800 miles; but allow for it two hours. From Shwaygyeen to Sz-mau, or Ez-mok (in the Yunan province), the south-west frontier town of China proper, is *the first division* of this proposed extension of the Indo-European wires to China, through the Burman Shan cities of Kiang-Tung and Kiang-Hung, along the existing Chinese caravan road which passes through them from Sz-mau to the more western Burman Shan city of Moni. And from Sz-mau to Hong-Kong, through the principal cities and towns of the Chu-Kiang, or Pearl and West River vallies, by either of the two main Imperial roads, is *the second division* of this very important and well-considered extension of telegraphy in the far east.

The distance from Shwaygyeen to Hong-Kong by that long-established and well-travelled route is about 1,475 miles, over which the wires will certainly carry forward such a message in about three hours. This will make eight hours and a half only for a long Government despatch between Galle and Hong-Kong. But allow even one hour and a half additional, in all ten hours, and the message will reach Hong-Kong from Galle in less time than the steamer takes to coal there, and *vice versâ*, thus anticipating the steamer's arrival at Hong-Kong by seventeen days, and overtaking her at Galle, on the homeward voyage, with the same number of days' later news from China.

Surely such an increase of the value and usefulness of the Indo-European telegraph, obtainable by comparatively so short a *land* extension of it, cannot be deemed undesirable, or undeserving of the prompt earnest support of both the Home and Indian Governments. Russia has extended her wires from Europe, through Siberia, to Novgorod, at the mouth of the river Toumen, in the Sea of Japan, and has still further developed her course of foreseeing policy and aggrandizing action in those distant waters by her designs upon the Japanese islands of Tsu-sima and Fatchu,* commanding the Strait of Corea. To these isles Russia has laid a telegraphic cable from Novgorod, not merely for rapid communication with the arsenal she is there forming, but also with St.

* See their official letter to the Secretary of State for India in Council of the 20th of January, 1863, printed in their private pamphlet V., "On the Commercial Opening of Western China, Overland from Rangoon."

* These two islands stand in the centre of the Strait of Corea, close to each other. Tsu-sima, the most northerly, is 45 miles long and 12 broad; while Fatchu is 15 miles long and 10 broad. The channel between them forms a magnificent harbour, and has a town on its shore with 30,000 inhabitants. Both the islands are otherwise well peopled, and abound with the luxuries as well as the necessaries of life. By fortifying Capes Aniva and Crillon, at the southern extremity of the Isle of Sakhalin, so as to command the Straits of La Perouse and of Sungar, both of which are now within her power, Russia will close the Sea of Japan and Gulf of Tartary against the world, and hold exclusive naval and military command of the entire western sea-borde of the Japan isles. The island of Quelpaert, on which we are *stated* to have had a military and naval station since 1847, in no way interposes against Russia in the direction here indicated; because Quelpaert lies considerably south and west of Fatchu and the Strait of Corea.

Petersburg, from the Japanese and Chinese outer waters generally.

The first two divisions of the proposed extension of the Indian wires to China—Shwaygyeen to Hong-Kong—being successfully constructed and in work, *the third division* will come to be entered upon—viz., from Hong-Kong to Shanghai. Carrying the wires through the open ports of Amoy, Foo-choo-foo, and Ningpo, and the principal cities and towns along that route, the distance would be about 850 miles: the telegraphic gain in time between Galle and Shanghai becoming full twenty-two days. And this *third division* accomplished, it will then remain to extend the wires still onward from Shanghai to Hankow, Tien-tsin, Pekin, and even Japan, as may promise to be most useful and remunerative, in reference to the support her Majesty's Government may give to the undertaking.

Of the portion of the Indian telegraph set up in the province of Pegu, the Commissioner stated in his annual reports of that province for the two years 1859-60 and 1860-61 as follows:—"There are two lines of telegraph in the province having eight stations—viz., one line from Rangoon, north-westward to Henzada, Mengyee, Prome, and Thayetmyo; the other line north-eastward from Rangoon to Pegu, Shwaygyeen, and Tonghoo. The first line measures 242 miles, and the second line 191 miles, making a total of 433 miles. The messages sent in 1859-60 were—Government, 2,071; and private, 6,853; the receipts for the former being £509, and for the latter £1,163: total, £1,672; while the total expenditure for the year was £5,806, or £4,134 in excess of the receipts." For such an unfavourable financial state of the Pegu branch of the Indian telegraph the province itself will never afford a remedy. This can only be found in the extension of its wires beyond it. And on this head the Commissioner at the same time thus wrote:—"During the passing year a line has been set up from Prome, in Western Pegu, across the Arracan mountains, to Sandoway, on the Bay of Bengal, a distance of 114 miles; and continued thence, by the island of Ramree, to Akyab, to bring the Pegu wires in connection with the telegraph of Calcutta and India generally; and there is no doubt that this junction with the Indian Imperial lines will cause some increase in the utility, and consequently in the receipts, of the Pegu lines."

Again it may be asked, how very much greater must not be the increase of that utility, and of those receipts, when these lines are extended eastward from Shwaygyeen to Hong-Kong, and to the other before-named important places of commerce in the "far east?"

The increasing importance of these propositions as regards commerce, united to their perfect soundness, must, ere very long, command the serious consideration of a British ministry. For, unlike some projects which have in late years received Government patronage, and are still sustained by it, what is here proposed is really honest in itself, simple in its character, inexpensive to execute, easy to preserve in working order, and so manifestly for the public good, that official action in it, if properly directed, can neither involve waste of the public money or ministerial discredit.

TAR AND INDIA RUBBER.

THE following extract from the important Report of Professor Miller, F.R.S., on the constitution of, and the effect of various solvents upon, virgin and masticated India rubber will be read with interest at the present juncture, when it is alleged that the application of tarred hemp to an India rubber insulated wire has promoted its destruction. These experiments were mostly made in our presence.

Experiments in Caoutchouc.

The caoutchouc of commerce is, like gutta, not a pure vegetable principle, and consists of a hydrocarbon of definite composition, mixed with a small quantity of resin, the amount of which varies in different specimens.

The following are the results of my analysis of a sample of pure unmanufactured Para rubber, compared with a sample of good sheet masticated or manufactured rubber.

	Virgin.	Masticated.
Pure caoutchouc	96·6	96·64
Moisture	1·3	0·82
Resin	1·8	2·06
Ash	0·3	0.48
	100·0	100·00

Or, deducting moisture and ash, its elementary composition gave—

	Virgin.	Masticated.
Carbon	85·82	85·53
Hydrogen	11·11	12·06
Oxygen	3·07	2·41
	100·00	100·00

Caoutchouc, like gutta-percha, is, as already stated, liable to deterioration, by exposure to the action of oxygen in the presence of solar light, but the gum is less rapidly injured if exposed to their influence in the native state, than if it has been previously masticated. When subjected to the action of air excluded from light, it does not experience any marked change, even during very long periods. It is, however, important to observe that the masticated rubber is much more porous than the unmanufactured caoutchouc. When immersed in water, caoutchouc absorbs a much larger quantity of this liquid than gutta-percha, and the masticated much more than the unmanufactured or virgin rubber. I subjoin the results of my examination of some samples submitted to experiment by Mr. L. Clark.

Virgin Para Rubber, finest quality.

500 grains of this was exposed in each experiment, in the form of a narrow tape-like strip of rubber, which had been stretched while hot and suddenly cooled. It was of a very pale brown colour. The various samples were submitted to experiment at the end of October, 1859, and were examined nine months afterwards (August 4, 1860).

No. 1, which had been exposed in netting, in the open air, to sun and rain, had become blackened and rotten, but was neither sticky nor crumbled, had increased in weight 34·5 grains, or 7 per cent.

No. 2 was exposed in the air and light, but kept dry in a bottle placed mouth downwards; it had increased in weight 14 grains, or 2·8 per cent. by absorption of oxygen, and had become brown, soft, and sticky, especially in the parts most exposed to light. It gave up 11·81 per cent. of an oxidized, soft, and viscous resin to alcohol. The annexed analysis will give an idea of the composition of the resin thus formed:—

Carbon	67·23
Hydrogen	9·54
Oxygen	23·23
	100·0

The proportion of oxygen differs a little in different samples.

No. 3, which was exposed to diffused light in fresh water in an open bottle, had become white and opaque from the absorption of moisture, and had increased 86 grains, or 17 per cent., but it had experienced no other alteration in chemical properties, and when dried resumed its original characters.

No. 4, exposed in sea water in an open bottle to diffused light, had absorbed 3·6 per cent. of its weight of water, but was only a little altered in appearance, not in chemical composition.

Masticated Rubber, Sheet, best quality.

A similar series of experiments was made simultaneously upon masticated sheet caoutchouc.

No. 1, exposed to sun and rain, had collected into a sticky mass, which had lost its tenacity and elasticity.

No. 2, in the inverted bottle exposed to diffused light and air, had increased in weight 8 grains or 1·6 per cent., and had collected into a lump, which was viscous, and had lost its elasticity, especially in the parts most exposed to the action of light. When treated with alcohol it was found to yield 12·64 per cent. of its weight of resinous matter to this solvent. These changes were in marked contrast to No. 3, which was kept in a glass bottle in the dark for the same period, but exposed to the air freely. It had increased in weight only 0·6 per cent., did not show any sign of alteration in tenacity or elasticity, and yielded to alcohol 2·0 per cent. of resin only.

No. 4, a sheet of the same rubber immersed in fresh water, open to the air and diffused light, had increased 87 per cent. by absorption of water, that is to say, it had nearly doubled its weight. It had become white, opaque, slimy, and sticky when pressed, and allowed water to be squeezed out by pressure. It lost weight rapidly by drying when exposed to the air.

No. 5, similar to the last, but exposed in sea water. It was slightly opaque and slimy, but had increased only 5 per cent. in weight by absorption. A second sample, in sea water in a closed

bottle, emitted a smell of sulphuretted hydrogen, and had gained 5·6 per cent. in weight by absorption. Its elasticity and tenacity were not impaired. The gradual permeability of masticated caoutchouc to water was further strikingly shown by enclosing a quantity of acetate of potash in bags made of sheet rubber and accurately sealed. They were then immersed in water, and at the end of nine months the salt in each of the bags was found to have become liquified by the water which it had absorbed, and the bags had in each case gained in weight several grains.

A similar Series of Experiments was made with Sheet Rubber, vulcanized.

1. The sheet exposed in the netting to the sun and rain had lost 2 per cent. in weight; it was scarcely less tenacious than at first.
2. A similar sheet in fresh water absorbed 19 per cent., but was not otherwise altered.
3. A similar sheet in sea water was rather more slimy and had only gained 1·6 per cent. in weight.

Each of the three substances, viz., natural, masticated, and vulcanized rubber were submitted to the action of the following solvents for nine months:—

A. Boiled linseed oil.
B. Unboiled linseed oil.
C. Stockholm tar.

The *virgin rubber* had resisted the action of the solvents almost perfectly, retaining its toughness, excepting in those parts which were above the surface of the liquid and exposed to light. In the tar this rubber had contracted spontaneously, but was still strong and elastic.

The *masticated rubber* was in each instance greatly swollen and gelatinized, and indeed in the case of the unboiled oil was completely dissolved.

The *vulcanized rubber* had also lost its tenacity, and had become swollen and gelatinous, but retained its form and a certain degree of elasticity.

A sample of India rubber cable (from Captain Galton), which contained six strands of copper wire, each coated with rubber, then bound round with tape and again with rubber, had experienced a singular change, having become, *where in contact with the wire*, quite glutinous and sticky. This change, however, did not progress in the specimen which I kept for some months in my room, but the viscosity on the contrary gradually diminished.*

REPORT OF THE ASTRONOMER-ROYAL TO THE BOARD OF VISITORS OF THE ROYAL OBSERVATORY, GREENWICH.

(Concluded from page 30.)

IX. Magnetical and Meteorological Instruments.—I have stated above that the excavation for the new magnetic basement was begun on January 25 of the present year. It is unnecessary to say that the observations of declination, horizontal force, and vertical force were at once suspended, and my remarks on the operation of the instruments apply only as far as January 25. All have been in excellent order. The vertical-force magnetometer still exhibits sometimes the "dislocations" in the photographic trace. There is no evidence, I believe, that these dislocations do not exist in the curves of every vertical-force instrument, for they are always accompanied with vibration; and no vertical-force instrument, I believe, except that of Greenwich, gives a trace strong enough to exhibit vibrations; and the dislocations, therefore, with any other instrument would appear merely as interruptions of the trace, and would not attract much attention.

In the preparations for mounting the instruments in their new location the following points are worthy of remark:—

The declination-magnet in the magnetic basement (a new 2-ft. magnet by Mr. Simms) is carried by a pier built of brick and slate, whose upper part, or suspension-piece, protrudes through the floor of the upper room, for the sake of giving greater length to the suspending-wire, and for making the suspension-piece more accessible. This instrument is used for photographic self-registration only.

Upon the superstructure of this pier is planted the original framed wooden stand for carrying the original 2-ft. magnet vertically above the photographic magnet. Hitherto this magnet has been so mounted that its attached collimator was right or left of it; it is now so mounted that the collimator is above or below it; and with this arrangement, on reversing the collimator, and giving the necessary movement for making the collimator-axis coincide with the axis of the theodolite-telescope, the magnet is still vertically above the photographic magnet in the basement.

The theodolite, with which the magnet-collimator is viewed, and with which circumpolar stars are also viewed, is in the same position as formerly; a brick pier being built up from the ground below the floor of the magnetic basement, through the basement, and through the floor of the upper room, to carry the theodolite.

For the support of the horizontal-force magnet a pier is built of brick, stone, and slate, which, like that of the declination-photographic magnet, projects through the upper floor into the upper room.

The suspending cords of these three instruments are of steel wire. I have seen no practical reason for objecting to the silk skeins; yet, on theoretical grounds, I have long since determined, when opportunity shall present itself, to make this change.

The new vertical-force instrument differs from the old one in the following points:—First, the length of the magnet is 18 inches instead of 2 feet; secondly, its ends are pointed—a construction indicated by Lamont as giving great magnetic power—which, however, is not successful in the present instance; third, the knife-edge is one continuous piece of steel; fourth, the whole of the frame which connects the knife-edge with the magnet is of iron. I am not able yet to say whether any practical advantage attends these modifications.

The new positions of the vertical-force and horizontal-force magnets are vertically below their former positions. That of the declination-magnet is about ten inches north of its former position.

I have now to mention a result of late observations which has given me great anxiety.

The variations in the power of the horizontal-force and vertical-force magnets depending on temperature were determined, several years ago, with very great care, by experiments in which the magnet was immersed in water of various temperatures. It is evident, however, that this form of experiment does not exactly reproduce the circumstances of a magnet whose temperature depends on that of the external atmosphere; and I have long contemplated experiments in which the magnet should be heated, not by water, but by air.

Opportunity seemed to be given by the command of the hot-air stove, constructed entirely of copper, and heated with gas, which was provided for the warming of the magnetic basement. I had a copper box prepared to fix on the top of this stove, containing facilities for the placing of the magnet (to be tried) in a definite position, for the distribution of the heated air over its length, and for reading three thermometers in different parts of its length. The degree of heat was regulated merely by turning the tap of the gas-pipe at the floor—a manipulation which could not affect any part of the apparatus. The stove was placed in a position convenient for producing deviation, by the magnet enclosed in the copper box, on the needle of the Kew unifilar.

The result of these experiments is, to give a co-efficient for temperature-correction four or five times as great as that given by the water-heatings. And this applies to both the magnets (horizontal force and old vertical force), in which I am able to compare the two systems of experiment. A large co-efficient is also given for the new vertical force magnet, though much smaller than that for the old one, when tried in the same manner.

I cannot discover any peculiarity in the apparatus which can produce the smallest error. The only differences between the modes of action in the two experiments are, that in the former, or water-experiments, the magnet was "end on" to the deflected magnet, while in the latter, or air-experiments, it was "broadside-on;" and that in the former experiments the magnet travelled round to a position definite with regard to the axis of the deflected magnet (in which case its power is measured by the sine of deviation), whereas in the latter it was stationary (in which case its power is measured by the tangent of deviation).

For the rotating cylinders upon which the photographic paper is placed, and which have hitherto been of glass, being merely glass shades selected with great care from the large stock of a vendor of glass ornaments, I propose to try ebonite. This material is very light, but is firm; it turns well in the lathe, and presents a very smooth surface. I expect that a little accuracy will thus be gained in the sub-divisions of the time-scale on the photographic sheets.

The Kew deflexion instrument is in good order, but with the same defect of plan which I described in my last Report, and which I have not had time to remedy.

The dip-instrument, and all its needles, are in good order. With regard to its needles, and to dipping-needles in general, and the change in the position which they take upon being merely raised and lowered, I suggested in my last Report that there appeared to be a small wandering of the magnetic axis (produced, I suppose, by the infinitessimal jar of raising and lowering the needle), and that the injurious effects of this might be removed if the breadth of the needle, instead of being in the plane transverse to the axis of rotation, were in the plane passing through the axis of rotation. I have accordingly had three needles prepared by Mr. Simms in this form, of the lengths three inches, six inches, nine inches respectively (the same lengths as those of the other systems of needles), with the same dimensions of axle and the same workmanship as in the other needles. And very lately I have had a numerical comparison made between the extreme discordances of the field-of-view readings of the needle-points (the microscopes remaining unmoved) produced by raising and lowering the needle usually five times,

* The quantity of viscous matter was too small to admit of satisfactory analysis. I ascertained, however, that no copper was present in the viscous mass, and that the wire was not corroded. I could not determine whether grease was present in small quantity, as was not unlikely.

sometimes four or three times, but as nearly as possible the same number of times in each class. The results are as follows:—

		Largest Values of Daily Mean of Extreme Value of Discordances, in Groups of 5, &c.		General Mean of Extreme Discordances, in Groups of 5, &c.	
9-inch needles	B_1 ordinary	19′	14″	8′	45″
	B_2 ordinary	12	14	8	45
	B_4 new flat	4	5	2	20
6-inch needles	C_1 ordinary	48	32	27	52
	C_2 ordinary	21	35	9	53
	C_4 new flat	7	12	3	36
3-inch needles	D_1 ordinary	12	21	7	56
	D_2 ordinary	14	6	7	24
	D_4 new flat	8	49	4	26;

and, combining the needles of different lengths but of the same class, the means of extreme discordances are—

For an ordinary needle	11′	45″
For a flat needle	3	27

It appears here that the greater part of the discordance is owing to a cause peculiar to ordinary needles, as distinguished from flat needles (which cause I still attribute to inconstancy in the position of the magnetic axis), whose action cannot be annihilated. After this I need not say that I consider it certain that the small probable errors which have been attributed to ordinary needles are a pure delusion. I know no instrumental determination in which, without any breach of faith, the wish for uniformity of results will be so certainly followed by uniformity of results, as in the determination of dip. I am proud to offer to the world the long series extending from 1843 to 1864, as one in which this wish has nowhere prevailed, and which I believe exhibits the genuine results of unbiassed observations made with the most accurate instruments that anxious care and the best mechanical skill could produce.

The self-registering apparatus for the record of results of the earth-current wires is ready in all important points, but its mounting is delayed for the completion of the magnetic basement.

The meteorological apparatus is in good order. Some of the instruments —the barometer, the dry and wet thermometers, the anemometers, and a pluviometer—are adapted (like the three magnetometers) to automatic continuous register as well as to occasional eye observation. Other instruments —as several pluviometers at different elevations—exhibit accumulations to be occasionally read by eye. Others—as the maximum and minimum thermometers in the air and in the Thames—register extremes only, and require to be read every day. The electrometers (which communicate with a wire that extends from a warmed glass pillar upon the electrometer mast to a warmed glass pillar upon the north-west turret of the octagon room) are only useful when the eye is turned towards them; until satisfactory means of self-registration can be arranged, these instruments are nearly useless.

I am preparing to erect near the entrance-gate of the Observatory a barometer for public information. Only the graduated face will be exposed. Upon this the scale of graduations will be much enlarged. Indexes are arranged for exhibiting the present state of the barometer, the last maximum, and the last minimum.

X. Magnetical and Meteorological Observations.—The barometer and dry and wet thermometers are read several times every day, and the maximum and minimum thermometers once every day, to the present time. The eye observations and the photographic record of the three magnetometers have necessarily been suspended since January 25, but the photographic record of the barometer has been continued to May 10, and that of the thermometers is still maintained. Dips have been observed twice each week, or oftener. Observations for absolute measure of horizontal magnetic force about three times in a month.

In the present year, commencing with January, 1864, sixty series of observations on twenty-three days have been made with the actinometer.

With the gratuitous assistance of the London District Telegraph Company and the Submarine Telegraph Company we every morning communicate to M. Le Verrier the state of weather and the readings of barometer and thermometer, which, with those from other parts of Europe, are published in the bulletin.

XI. Reduction of Magnetical and Meteorological Observations.—The equivalents for eye observations of the three magnetometers, and the temperature corrections for two, are applied as far as the suspension of photographic records on January 25; the reading for astronomical meridian is reduced and applied to December 31, 1863. The time-scales are attached to the photographs as far as December 31, 1863; the new baselines for the declination and horizontal force to June 30, 1863, for the vertical force to December 31, 1863. The deflection observations are reduced to December 31, 1863. The dip observations are reduced to the present time.

The mean magnetic declination for 1863 is about 20° 46′; the diminution from the preceding year about 6′. The mean dip for 1863 is about 68° 4′. The diminution from 1862 appears to be about 7′. The dip at the present time appears to be 68° 2′; but this depends partly on C_1, which always gives a large result. It is remarkable that this is the needle whose magnetism, as above stated, appears to be so unsteady.

The barometer-photographs are in the same state as the vertical-force photographs upon the same sheet, to the end of 1863. No step of reduction is taken for 1864.

The thermometer-photographs are nearly in the same state.

The vane of Osler's anemometer made about +28·5 complete revolutions in the year 1863; the largest number that we have yet observed.

In the last report, I alluded to the numerical discussion of the magnetic storms, 177 in number, registered from 1841 to 1857; the treatment of which was then far advanced. In the last autumn, I finished the discussion of these: the results have been placed before the Royal Society, and are printed as a memoir in the Philosophical Transactions. They appear to me entirely to support the idea that storm-disturbances cannot be explained by sudden magnetic attractions or sudden galvanic currents, but require the supposition of currents, like air-currents or water-currents, upon the surface of the earth.

XII. Printing of Magnetical and Meteorological Observations.—I have thought it desirable to commence the printed record of the observations of 1862 with an introduction at considerable length. The last detailed introduction is that in the volume for 1847 (the last separate volume of detailed magnetic and meteorological observations); and, though changes in instruments and methods have been noted in the briefer introductions preceding the "Results of Magnetic and Meteorological Observations" attached to the Astronomical Observations, yet it appeared advantageous now to collect the results of all, and to exhibit fully the present state of the magnetical and meteorological establishment. The manuscript is in the printer's hands, and the printing is in progress.

The indications of the magnetometers are printed in the same form as in preceding volumes commencing with 1847; exhibiting the numerical values, expressed each by its proper scales, of the ordinates of all the salient or conspicuous points of each photographic curve. The printing of these is very nearly finished for 1862. The other magnetic observations are prepared for printing in different degrees of detail; the manuscript is in the hands of the printer. An appendix contains the abstract of the reduction of the observations of magnetic storms (to which I have alluded above) in a form intermediate between the exhibition of instrumental indications and the analysis in the Philosophical Transactions; the printing is far advanced. The meteorological observations for 1862, in abstract only, are printed.

As the long introduction, and the storm abstracts, increased the size of this portion of our printing, I have deemed it expedient, for 1862, to direct that it be bound in a separate volume. The number of copies is 600, of which I propose that 350 be considered as a second part of the astronomical volume, and that 250 be circulated separately as heretofore.

For 1863, the indications of declination magnetometer are prepared to Feb. 26, those of horizontal force to May 31, and those of vertical force to July 31. The meteorological abstract is more than half finished; the following tables nearly complete.

It is known to the visitors that I have every year prepared photographic copies of the photographic curves, for future use or communication to others. These copies can only be formed by the transmission of sunlight through the originals, and, in order to give the desired vigour and clearness to the copies, it is often necessary to touch the originals with sepia or other dark pigment. It has been matter of great regret to me that the delicacy of the original is frequently much injured by this process. I have at length devised a method which removes all difficulties. An apparatus is constructed, consisting of a horizontal looking-glass and a sheet of clear glass erected over it in the position of a desk. The photographic sheet is laid upon this desk with its face downwards; the photographic curve is seen in the utmost perfection by light reflected from the looking-glass and transmitted through the paper; and the sepia is laid on the back of the paper, without touching the original photographic trace at all.

Two copies of each of the photographic curves for declination and horizontal force have been taken to December 31, 1861, and two for vertical force to April 30, 1862.

XIII. Chronometers, Communications of Time, Longitudes, &c.—The number of chronometers on hand at the date of this report is 168; of these, 101 are the property of Government, and 67 are on the annual competitive trial. The whole of the latter and a portion of the former are compared every day with one of the galvanic clocks, sympathetic with the normal mean-time clock; the remainder are compared with it once every week. Every chronometer is tried for some weeks in the heat of the chronometer oven.

All decisions on the merits of chronometers offered to the Government for purchase, and on the merits of chronometers rated in the annual competitive trial, are referred to me; and the repairs of chronometers belonging to the Government are effected entirely through me.

The system of galvanic clocks (containing among others the normal clock, the chronometer clock, and the large clock at the entrance gate), are all simultaneously adjusted to time by the use, when required, of a galvanic force, which may be kept in action during any arbitrary time, to accelerate or retard the vibrations of the pendulum of the normal clock. Another common clock has lately been fitted with contact springs, to enable it to give the currents at every second when the normal clock is for a time disabled.

The time-signal-ball at Deal is dropped daily by a galvanic current automatically given by the normal clock; and from the first, very few

failures have arisen from defect in the observatory apparatus. Failures have usually arisen (and, in the late disturbed state of the South-Eastern station, more frequently than usual) from defects in the connexions of the railway telegraph. Time-signals are sent daily to great distances, as Glasgow and Cardiff, and on the principal railways in various directions. Time-signal-guns are fired daily at Newcastle and Shields. The Post-Office clocks are regulated mechanically, and signals are sent for regulating the Westminster clock; and all these, as well as the Deal ball, automatically report to us the success of the effect of the current which left the Greenwich clock. I shall advert below to the failure of my proposal for hourly time-signals on the start point.

In these various operations, about one-fourth of the strength of the observatory is employed. Viewing the closer dependence of nautical astronomy upon accurate knowledge of time, there is perhaps no department of the observatory which answers more completely to the original utilitarian intentions of the founder of the Royal Observatory.

I expect that, in the latter part of the summer, steps will be taken by Mr. Otto Struve for the telegraphic determination of the differences of longitude between Greenwich and some station on the Continent, and between Greenwich and some point near Milford, as portions of the great arc of parallel which is to extend from Orsk on the river Oural, to Valencia. The initiation of this enterprise was made by Mr. Struve, and much of the primary work was done by Mr. O. Struve. I hold it to be my duty therefore in no way to interfere with Mr. O. Struve's plans, but to place the observatory, and myself, and the influence which I may command among the telegraphic or other institutions of the country, entirely at his service, and, as a zealous subordinate, to take every possible measure for carrying out his design.

XIV.—Personal Establishment.—The persons employed as assistants are the same, and with the same ranks as at the last report; Mr. Edward James Stone, M.A., Fellow of Queen's College, Cambridge, is confidential assistant; Mr. Dunkin is charged with the altazimuth; Mr. Ellis and Mr. Criswick with the chronometers and time-work; Mr. Carpenter with the equatoreal, and with the care of manuscripts, library, distribution of observations, &c. Mr. Lynn, B.A., University of London, has the control of the supernumerary computers. Four or five computers are usually attached to the astronomical department. Mr. James Glaisher, F.R.S., second assistant of the Observatory, superintends the magnetical and meteorological department, aided by one assistant, now Mr. Nash, and by three or four supernumeraries.

I am ultimately responsible for every part of the work performed at or for the Observatory.

XV. Extraneous Work.—I have not, in the past year, sought for the Observatory any extraneous work, although in my own person I have found it difficult to avoid devoting a portion of my time to the assistance of the Government in some small matters applying to standards of measures and weights.

This, however, may be a proper place for referring to other works connected with the Greenwich observations. Mr. H. Breen, formerly assistant, but who had retired from the Observatory, desired to complete certain numerical investigations, and the Admiralty, after calling for my opinion on some points, have sanctioned the expense. The first was a re-determination of the moon's parallax, by comparison of the observations of declination made at the Cape of Good Hope, principally with those made at Greenwich, but partly with those of other British observatories; the results of this are printed in the memoirs of the Royal Astronomical Society. The second was a determination of the moon's diameter as inferred from occultations at Greenwich and Cambridge; the manuscript computations are still in my hands for revision, as soon as I can find leisure for that purpose. The third is a general reduction of Bradley's unpublished Greenwich observations from 1743 to 1750; the attested copy of the manuscript is lent to Mr. Breen for this purpose, and preparations for the calculations are begun, but no part except perhaps some auxiliary tables is yet actually computed.

XVI. General Remarks.—The visitors will doubtless have remarked that the hope which I expressed in my last report, of shortly bringing up the reductions to their usual state, has not been disappointed. The astronomical reductions have been brought up to a state more advanced than usual; the magnetical reductions are not quite so forward. This considerable advance upon the state of things in 1863 has been gained principally in consequence of our having no large extraneous work. Observations have been restricted where it could be done without loss of anything essential, yet the whole number of observations scarcely differs from that of the preceding year. The assistants have honourably used their best efforts to urge the work on in an orderly and rapid course.

The whole amount of labour in the year can scarcely be gathered even from such a detailed report as that which I have offered. The time consumed in reductions or comparisons connecting the past of Greenwich with the present; the correspondence with contemporaneous institutions; the responses to applications or inquiries of irregular character, by no means confined to astronomical, magnetical, or meteorological subjects; the preparations of new introductions, descriptions, or memoirs; the arrangements of manuscripts, books, and money accounts; and the general administration; occupy a far larger proportion of our time than could be conjectured by any person who has not had the experience of an establishment, old, active, and widely connected. The part of these labours which falls on myself has been felt in the past year as heavier than usual.

Before closing this report I take the opportunity of placing on record some plans of proposed action, which I am unable to carry out at present; but which, as I trust, with such modifications as experience may suggest, will be adopted for effectual use at some future time. They relate to the system of hourly time-signals proposed for exhibition at the Start Point.

It will be remembered by the Board of Visitors that, after consideration of the reasons which I adduced and the methods of galvanic communication and manipulation which I explained, the Board, at their visitation of 1862, deputed a selection of their members, accompanied by myself, to wait on his Grace the First Lord of the Admiralty, and to request his favourable attention to the proposal; and that in the course of the summer of 1862 an answer was received, conveying the substance of communications referring to this proposal which had passed between the Board of Admiralty and the Board of Trade, of which the conclusion was that the Board of Trade possessed no funds applicable to the defraying of the expenses attending the execution of the scheme. This answer was not laid before the Board of Visitors or known to myself till the visitation of 1863. As it did not fully explain the intentions of the Board of Admiralty, I applied to them in the autumn of 1863, requesting to be informed whether the Admiralty considered as possible the establishment of these time-signals under their own authority; and I received their reply that they do not at present contemplate that measure.

Trusting that the establishment of these signals is only deferred for a few years, and thinking it probable that advantage may result to the system which will hereafter be adopted, from a publication of some details of the plan on which I had proposed to act now, I will here state the general principles of the arrangement on which I had provisionally decided.

The Admiralty possess telegraphic wires passing underground from the Admiralty Telegraph-office in Whitehall through the principal street of Deptford, towards Deptford Dockyard, Woolwich, and more distant places. The Royal Observatory possess telegraphic wires passing from the Observatory to a house in Deptford called Gothic House, through which one of the Admiralty wires is led; and here, at any moment, such communications of wires can be made, that the galvanic currents from the Admiralty will all pass to the Observatory and back to Gothic House (by what is technically called "a loop"), and thence proceed towards Deptford Dockyard and Woolwich.

When an interruption is made at the Observatory, then currents can be sent direct from the Observatory to the Admiralty Telegraph-office.

The wire of the Deptford speaking-instrument in the Admiralty Telegraph-office can be joined with a wire of the Devonport speaking-instrument in the same office. The wire from the Telegraph-office to Devonport is continuous, and is good, liable only to some interruptions from occasionally receiving the spray of the sea beyond Exeter.

When these connections are made there is unbroken metallic communication from the Royal Observatory to the Admiralty-office at Devonport: sufficiently good to ensure the transmission of Greenwich signals with the regularity required for giving the information by which the Devonport superintendent can adjust his clock; and also sufficiently good to ensure the transmission of automatic signals from the Devonport clock to Greenwich, by which the officers of the Royal Observatory will see the error of the Devonport clock; but not sufficiently good to ensure the regular dropping of a time-signal at the Start, if wires should be continued from any part of the Devonport telegraph-wire to the Start.

The distance, however, from Devonport to the Start is so much less, that it may be expected that no difficulty will be experienced in dropping a time-signal at the Start by the agency of a galvanic battery and automatic clock at Devonport.

The first section, then, of the proposed operations must consist in such arrangements as will secure the accuracy of a clock at Devonport, and the second section must consist in such arrangements as will secure the accuracy (by automatic action of that clock) of the signal-drop at the start, and will also secure a register at Devonport (by automatic action of the Start mechanism) of the actual success of the signal-drop, in a form which will admit of convenient transmission to the Royal Observatory of Greenwich.

For the first section three arrangements are to be made:—1. About the time of each of the proposed communications from Greenwich to Devonport, or from Devonport to Greenwich (in all, three times or four times every day), for a few minutes at each time, an automatic clock at Greenwich must interrupt the Greenwich loop, and must connect the Greenwich Motor clock with the Deptford wire to the Admiralty; and an automatic clock at the Admiralty must interrupt the communications of that Deptford wire with its speaking instrument, and of one Devonport wire with its speaking instrument, and must connect the Deptford wire with the Devonport wire. 2. At the times arranged for signals from Greenwich to Devonport, the Motor clock at Greenwich must for an instant automatically take its wire from earth, and connect it with a galvanic battery. 3. At the times arranged for signals from Devonport to Greenwich, the Devonport clock must for an instant automatically take its wire from earth and connect it with a battery. All these arrangements are very easy, and their action is practically infallible.

The Devonport clock would probably require a small mechanical correction every day (to remove the error arising from unsteadiness of rate, which error the attendant would ascertain by observation of the Greenwich signals). This is best done, as at Greenwich, by fixing on the pendulum a magnet, of which one pole swings above a galvanic coil; a galvanic current, sent at

pleasure through the coil, produces attraction or repulsion, according to the nature of the current sent; and the clock is accelerated or retarded. The current must be kept in action till the clock error is perfectly corrected.

In this manner, it was presumed, accuracy would be insured in the state of the Devonport clock sensibly equal to that of the Greenwich Motor clock; and thus Devonport might be adopted as basis for the operations by which the Start time-signal would be actually dropped.

For the second section the arrangements would be the same as those between Greenwich and Deal. There must be a clock at the Start, by which the resident at the Start would be guided in order to raise the Start signal at the proper time before each hour; there must be a relay and a local battery; the Devonport clock, by mechanism similar to that of the Greenwich Motor clock, must automatically send a current accurately at every hour, which will work the relay and put the local battery in connection; and the action of the local battery must withdraw the detent on which the time-signal is lodged, and thus drop the signal; and the signal, shortly before reaching its lowest point, must (by what is called a "tapper-apparatus") so change the connections of the battery that an instantaneous current will be sent to Devonport. These arrangements are found, in practice, to work without failure.

It was proposed that the time-signal at the Start should be a skeleton-ball about eight feet in diameter, dropped through a space of twelve or sixteen feet. The locality selected for it is a rock behind the Start lighthouse, called "The Boy." The height of the mast on which it should be raised would be determined after inspection from the sea; but no great height would in any case be necessary. It was proposed to commence with day-signals only, but night-signals would be given by a mere change of galvanic communications at the Start, which would enable the galvanic current to drop a small weight, whose fall would fire a quantity of gunpowder sufficient to produce a flash visible at the distance of several miles.

For the Devonport record of the currents sent by the action of the tapper-apparatus at the Start the following mechanism was proposed:—The Devonport clock was to give rotation to a small barrel, perhaps three inches long and three inches in diameter, covered with paper. This barrel was to revolve in a time differing from 1h. by a small quantity, say by $\frac{1}{500}$ part, which would easily be given by the 60-minute spindle of the clock, carrying a wheel of thirty teeth acting in one of twenty-nine teeth, the latter wheel being fixed to one of thirty teeth acting in the barrel-wheel of thirty-one teeth. The Devonport clock also was to give slow motion by a screw to the frame carrying an indicator, which would be made to travel nearly from one end of the barrel to the other in twenty-four hours. That indicator would be made to impress a point on the barrel by the instantaneous current from the tapper-apparatus. It will be seen that the twenty-four signals given in the course of one day, if at perfectly uniform intervals, describe on the barrel a spiral very little inclined to the axis. Any departure from uniformity to the extent of three seconds of time would immediately be visible to the eye, and this would be sufficient to give evidence on the correctness of management of the ball. At the end of twenty-four hours exactly the barrel would have performed $24 + \frac{24}{500}$ revolutions. In preparation for the commencement of a second day the attendant must draw back the travelling indicator frame to the beginning of the screw, and then the indicator would in the course of the second day describe another spiral at the distance $\frac{24}{500} \times$ circumference of barrel from the former. This retraction of the indicator-frame is the only daily operation, referring to the register, which is required from the attendant. At the end of each month the barrel must be removed and replaced by another—the paper covering is then to be taken off and sent to the Astronomer-Royal. For the indicator I proposed to use a mechanism (suggested to me by Professor Wheatstone) in which the bottom of a small cistern of ink is perforated with a single hole, too small to permit the escape of the fluid ink; the action of the galvanic current thrusts a small wire through this hole, and the end of the wire carries a small film of ink, which impresses a dot upon the barrel-paper.

In selecting a course for the telegraph-wires from Devonport to the Start, it was proposed, under the advice of the best telegraph engineers, not to take the shortest line (which would be, to return towards London as far as the Kingsbridge-road station, and then to pass by an inland road directly towards Kingsbridge and the Start point), but to make use of existing poles to Newtown-junction, Torquay, and Dartmouth, from which place the extent of telegraph line upon new poles would be small.

The following collateral advantages would attend the establishment of this system of signals:—Accurate time-currents would be given at Devonport, which could be made subservient to the public exhibition of time-signals, either at Mount Wise or on the Devonport Column. A commencement would be made of coast-telegraph, available for military purposes. Facilities would be given for a commercial telegraph from the Start Point to Dartmouth, much desired by persons connected with the mercantile marine.

G. B. AIRY.

May 23, 1864.

SCIENCE HONOURED.—We find that M. Ruhmkorff has received the prize of Napoleon III. (50,000f.) for the finest application of electricity, on account of the induction apparatus which bears his name. He has also received the great gold medal of the order of merit from the King of Hanover.

CORRESPONDENCE.

SMITH'S ELECTRIC TELL-TALE.

To the Editor of the TELEGRAPHIC JOURNAL.

SIR,—Your notice of Mr. Smith's Tell-Tale, in the *Telegraphic Journal* of the 16th, has been duly appreciated by me. You will, therefore, in future discontinue inserting my advertisements or forwarding the paper.—I remain, Sir, yours obediently,

J. SAX.

[We give publicity to the above letter, as it is distinguished by a candour in the expression of opinion seldom met with in these days of disingenuousness. Mr. Sax is at liberty to make what use he pleases of our notice of Smith's Electric Tell-Tale. It has always been our endeavour to faithfully represent telegraphy, and to make the *Telegraphic Journal* a record of electrical progress; it is, therefore, very encouraging to learn that our labours are "duly appreciated."—ED. T. J.]

INDIA RUBBER COVERED WIRES.

To the Editor of the TELEGRAPHIC JOURNAL.

SIR,—The extraordinary, rapid, and utter failure of the twenty miles of india rubber covered cable, forwarded to India some three years ago, is a subject of immense importance at the present moment, when it is in contemplation to embark in extensive submarine undertakings. Great hopes were entertained at the time that the above cable would be the means of re-establishing confidence in the permanency of deep sea telegraphy, and not a word was said as to the plan adopted for serving the cable with tarred hemp. During the process of sheathing at Mr. Henley's works, indeed, the patentees suggested the saturation of the hemp sheathing with a composition of tar and cork, and a specimen of such a cable now lies before me. It is evident that the "MANUFACTURERS OF THE CORE" endeavour to fix upon Sir W. O. S. Brooke the responsibility of the failure. It appears to me unjust to do so. The following is an extract from a letter published by those gentlemen in March, 1863, in which there is no reference whatever to the tarred hemp:—

"After undergoing the testing, the core was forwarded to the works of Mr. Henley, North Woolwich, in order to be finished off with a sheathing of spiral iron wire—a process, by the way, which we consider highly injurious to any core of whatever material made." *No complaint of the serving with tarred hemp!* There can be no doubt but that this untoward event will greatly militate against the adoption of the material for submarine telegraph purposes—a material, if properly and skillfully treated, which possesses all the elements conducive to success.—I am yours, &c.,

A. J. T.

TAR AND INSULATING MATERIALS.

To the Editor of the TELEGRAPHIC JOURNAL.

SIR,—As it appears that Stockholm tar is fatal to india-rubber insulation, I am curious to know what will be the effect of the large quantity of that material which is now being introduced between the insulating layers of gutta-percha in which the conducting wire of the Atlantic cable is enveloped. My experience leads me to denounce the introduction of tar as a component part of a gutta-percha core. The *invalid* which lingers between Malta and Alexandria affords an instance of the injudiciousness of employing tar when it is known that its insulating capacity only lasts for a brief period. I am informed that it is adopted simply because it is a cheap insulator, and may be depended upon for some weeks, at least as far as the contractor's guarantee extends. I hope that the few observations I have made will induce some of your readers to enlighten us upon the above, by no means unimportant, subject.

CATO FIDELE.

TAR AND INDIA RUBBER.

To the Editor of the TELEGRAPHIC JOURNAL.

SIR,—One would have thought that the extensive experiments made under the direction of the Board of Trade by Professor W. A. Miller, Mr. Latimer Clark, and Mr. Owen Rowland, with the view of ascertaining the effect of various solvents upon gutta percha, india rubber, and other materials, would have rendered it improbable that such an eggregious error should have been perpetrated as to enclose a masticated rubber insulated wire in a serving of tarred hemp. I have looked over a communication addressed to a late contemporary by Messrs. Wells & Hall, and dated the 30th March, 1863, and no protest whatever is made against the enclosing of their India rubber core in tarred hemp sheathing. In fact, I believe that one of the patentees stated that there was no danger to be apprehended from the application of tar to the core manufactured by his firm, and I know that on a previous occasion tarred hemp was employed as a sheathing to a short length manufactured for Government purposes. It appears to me, Sir, strange that in telegraphy a conduct should be pursued by manufacturers so diametrically opposed to that adopted in other branches of industry. The manufacturers of the cable in question must have known, or at least ought to have known, that the enveloping of their core in tarred hemp must have proved fatal thereto. What says Professor Miller?—"The *masticated rubber* was in each instance greatly swollen and gelatinized, and indeed in

the case of the unboiled oil was completely dissolved." But then, again, what are we to say of the total destruction of the virgin rubber with which the wire was primarily coated in the above instance? I believe that the pure Para rubber (as it is called), in the cable manufactured for the India Government, of which so much has been said, was thoroughly gelatinized and its insulation completely destroyed, although Professor Miller's experiments appear to prove that the solvent powers of Stockholm tar did not affect the composition of the material in the least, as it did that of the masticated rubber as described. I write in no unfriendly feeling, but on the reverse, my object is to invite enquiry, which I believe must culminate in beneficial results to the science at large—"a consummation devoutly to be wished." In conclusion, allow me to express an opinion which I believe is generally admitted to be correct, namely that "Telegraphy is frightfully hampered by patents."—Yours truly,

18th July, 1864. OMICRON.

INDO-EUROPEAN TELEGRAPH.

To the Editor of the TELEGRAPHIC JOURNAL.

Constantinople, 11th July, 1864.

Sir,—I observe by your paper of the 25th ult., that you have inserted extracts from the Constantinople correspondent's letter to the *Daily Telegraph*, dated 9th of June, relative to the Indo-European Telegraph, &c. I therefore request you to be good enough to insert my reply thereto in your journal. Your early attention will much oblige, yours faithfully,

L. WALTER COURTENAY,
Commissioner to the Indo-European Telegraph.

To the Editor of the DAILY TELEGRAPH.

Constantinople, 9th July, 1864.

Sir,—My attention has just been called to a letter of 9th of June, from a correspondent at Constantinople, which appeared in your impression of 21st ult., and in which my name has been mentioned.

I should not have taken the slightest notice of the matter—the value of this attack, and the source from which it emanates, being locally well-known, and correspondingly appreciated—were it not, that the assertions, circulated in your widely diffused columns, at once acquire an importance which would not otherwise belong to them, and are calculated to mislead the public at home.

He states, that "Mr. L. W. Courtenay had applied for the use of an office in the European Telegraph Department; that this had been refused, and one had been offered at the Scutari office."

Now, inasmuch as the office destined exclusively for the reception and retransmission of the Indo-European telegrams, is according to Art. 6 of the Convention, to be quite separate from the present European Telegraph Department, and that, owing to technical difficulties, no decision has been as yet come to, as to whether such office is to be at Scutari, Stamboul, or Pera, nothing has been done in this question. No official application has been made, therefore no refusal can have been given. I have mentioned the desirability of my having an office in this special department to His Excellency Sir Henry Bulwer, in a memorial addressed to him, and lately *in conversation* to the Ottoman Director General of Telegraphs, and so far from being refused, no opposition whatever was made; the technical difficulties once removed, the special office will certainly be at Stamboul or Pera. In the meantime I have given up two rooms in my own house at Pera, and the only person inconvenienced is myself.

With regard to Mr. O'Connor, I am so fully convinced of his merits, that I have urged, and am still strongly urging upon the Ottoman administration, the expediency of his being appointed *their* superintendent of the special office above alluded to, in which capacity all the Indo-European telegrams will pass through his hands, and his long experience of the practical working of a telegraph office, and of the management of a large staff of "employés" in this country, will no doubt prove him to be the best man that could be selected. I have every reason to believe, that my representations in this direction will prove successful.

Your correspondent is further in error as to my being "traffic manager." I have been appointed "Commissioner" for the "Indo-European Telegraph," and my duties are altogether separate from those which Mr. O'Connor will have to perform, if appointed.

As throwing light upon the *animus* of the letter, I think it right to mention the fact, that your correspondent was employed by me for a short time as temporary amanuensis, and hence may have become superficially acquainted with the telegraphic details, which he has communicated to you, some of which are correct, or rather were so *three months* ago, but many of which are entirely inaccurate.

My name having been so prominently brought forward must be my excuse for troubling you with the above explanation, and I rely on your courtesy in affording it a space in your valuable paper.—I have the honour to remain, Sir, your obedient servant, L. WALTER COURTENAY,

Commissioner to the "Indo-European Telegraph."

AEROSTATIC RAILWAY.—From the *New York Sun* we learn that M. Gourand, vice-consul of France for Rhode Island, has made application for a patent for his aerostatic railway, to be worked by atmospheric force upon inclined planes of wire suspended in the air. It is proposed to apply it to street railways for crowded thoroughfares in populous cities.

TELEGRAPHIC NEWS.

ELECTRICAL FORCE.—At the Royal Society, on the 16th ult., Sir Snow Harris, F.R.S., communicated a paper detailing "further inquiries concerning the laws and operation of electrical force." In this paper the author endeavours to definitely express what is meant by *quantity of electricity, electrical change*, and *intensity*. He also enumerates formulæ, as embracing the general laws of quantity, surface, boundary, extension, and intensity, practically useful in deducing the laws of statical electrical force. We shall endeavour to lay before our readers the whole of this interesting paper shortly.

SPANISH CORRESPONDENCE.—The Submarine Telegraph Company gives notice that messages intended for places where there are no telegraph stations, must be addressed by post from the nearest known station, the use of "expresses" and "estafettes" having been abolished by the Spanish administration; and that messages containing the same subject-matter, addressed to more than one person in the same town, can no longer be delivered at a charge of sevenpence per copy. Henceforth each copy will be charged for at the same rate as that paid for the original message.

DAMAGE TO A SUBMARINE CABLE.—On the 17th inst., the brig Caroline of London, arrived in Ramsgate Harbour, and reported having damaged with her anchor the submarine cable lying between Dover and Ostend. On the following day she left Ramsgate for the purpose of picking up the cable, which has been successfully repaired. The Submarine Telegraph Company, in consequence of the frequent damages caused by ships' anchors on the Dover coast, had a short line carried from Ramsgate across the Goodwin Sands, and joined to the main cable between Dover and Ostend, about twenty miles from land; so that it is hoped that for the future these obstructions from anchors will be avoided. The whole business of the company is now being carried along the new line, and should any accident occur the old branch to Dover will be available.

W. F. COOKE.—We have to thank an esteemed correspondent for an interesting account of some pleasing festivities which took place recently at Castledeudraeth, in Merionethshire, North Wales. The festivities took place on the marriage of the eldest daughter of W. Fothergill Cooke, Esq., of Aberia-hall, in that county, to Major Andrews, of the R.A. Mr. Fothergill Cooke, we need hardly inform the telegraphic world, is the gentlemen to whom we are indebted for having practically introduced and carried out the electric telegraph. Our correspondent adds, that Mr. Fothergill Cooke is beloved as a liberal landlord, a generous master, and an excellent neighbour in his adopted country, where he has experienced complete restoration to health, after many years of severe illness. The children of the various schools in the neighbourhood were entertained upon the occasion with a liberal supply of good things, in commemoration of the happy event.

THE OCEAN TELEGRAPH COMPANY'S CABLE—A scheme is in course of realisation, under the direction of Captain Rowett, for connecting France with America by a submarine line. The following is the form of Captain Rowett's proposed cable:—Diameter, about one inch. There will be only one copper conductor, and this is to be imbedded in virgin india-rubber. Hitherto telegraph wires have been bedded in manufactured rubber, in which it is difficult to exclude impurities. These have been acted upon by sea-water, which obtains access to the wire, and impairs its value as a conductor of electricity. This imperfection Captain Rowett hopes to remedy, by employing virgin india-rubber, to be covered with hemp ropes, and treated with a compound invented especially for the purpose. It is estimated the cable will cost £150 a mile, and that the line can be completed and opened for traffic for a sum not exceeding £500,000.

THE WIMBLEDON RIFLE COMPETITION.—On Saturday the 16th instant, a perfectly new competition at Wimbledon, though it has been successfully tried at other meetings, was the volley-firing for the sum of £50 given by the proprietors of the *Saturday Review*, and four set of electric bells given by Count De Gendre. These bells, it may be observed *en passant*, are for the purpose of communicating between the firing-point and the mantlet, to warn the marker when a shot is about to be fired, and receive instantaneously from him a signal that he is on the alert. They have been in successful operation at the Swiss targets during the meeting. Some such means of communication is very necessary with the Swiss or with cardboard targets, through which a bullet passes with so little noise that it might escape the notice of the marker. When a miss occurs the marker at once makes an appropriate signal, which satisfies the rifleman that his shot has been noticed. It is but fair, however, to say that an equally efficient and far less expensive system of telegraphy has been in operation at Captain M'Gregor's cardboard, sweepstakes targets, 200 and 500 yards, and at the "coming man" target. His plan is to have a small mirror fixed above the mantlet in such a way as to enable the marker to see what is going on at the firing point. The officer keeping the register is supplied with a sheet of cardboard, white on one side and black on the other. When a shot is about to be fired, the white side of the cardboard is turned towards the mantlet. The marker acknowledges this by a recognised signal; when the shot is fired he sees the smoke, and either marks the spot hit or indicates that it is a miss. So well has this principle answered that markers unused to the system not only make no mistakes, but in more than one instance at the "coming man" target have instantly detected a shot that ought to have been fired at the adjoining 200 yards sweepstakes targets.

TELEGRAPHS IN NEW SOUTH WALES.—The only telegraphic works at present in progress in this colony are three branch lines, which are being carried out, under an arrangement with the residents in the several districts, that the Government shall receive five per cent. on the outlay. On the line from Braidwood to Queenbeyan a distance of fifteen miles has been cleared, and holes for the posts have been sunk for a distance of thirteen miles. The posts are all erected on the line from Deniliquin to Hay, and fifteen miles of wire suspended. The line from Wellington to Dubbo has been commenced. The estimates for 1864 being at length passed, tenders will shortly be called for new lines, for which money has been voted. These consist of extensions from Mudgee to Murrurundi, and from Braidwood to Arabren, and the continuation of the line to Cooma.

THE ELECTRIC AND INTERNATIONAL DRAMATIC CLUB.—On Thursday evening, the 14th inst., the members of this very excellent club of amateurs gave a benefit performance at the Cabinet Theatre, King's-cross, in aid of Mr. James Crawley, who has been suffering for some time from a severe and painful illness. The performance commenced with the domestic drama, "The Rent Day." Mr. James Cook played the part of *Martin Heywood* with feeling, and was much and deservedly applauded. Mr. Perry, as *Old Crumbs*, executed his rôle with care and energy. Mr. Brandon made a very good *Toby Heywood*, and will improve with practice. Mr. W. Coleman is an exceedingly clever low comedian, and his representation of *Bullfrog* was characterised by rare fun and drollery—the scene in the bedroom was especially effective, and elicited rounds of applause. Mr. Garrard was well up in the character of *Silver Jack*, and acquitted himself creditably. Mr. Tripe looked and played the part of *Grantley* well. Miss Agnes Burdett, as *Rachel Heywood*, acquitted herself in first-rate style; indeed, her acting throughout the piece was that of a finished and accomplished actress. The part of *Polly Briggs* was very nicely played by Miss Pearman. The performance of "Love in Humble Life" was very creditable; the acting of Mr. F. Perry, as *Rouslaus*, and Miss Agnes Burdett, as *Christine*, calling for especial commendation. The "hit" of the evening, however, was the popular farce, entitled "A Rough Diamond." Mr. Coleman as *Cousin Joe*, and Miss Agnes Burdett, as *Margery*, kept the audience convulsed with laughter the whole of the time they occupied the stage. Messrs. Garrard and Tripe, as *Sir William Evergreen* and *Captain Blenheim* played carefully and well, as also did Mr. Tranfield, as *Lord Plato*, who gave promise of future excellence. At the conclusion of this piece Mr. Coleman and Miss Burdett were called before the curtain and received a well-deserved ovation. The proceedings throughout the evening were very gratifying. There was an absence of that ungentlemanly conduct of which we had to complain on a former occasion, and "all went merry as a marriage bell." It afforded us singular pleasure to note the presence of several of the chief officers of the Electric Telegraph Company in the boxes, and we are persuaded that their encouragement gave a zest to the performance throughout.

COXWELL'S BALLOON.—As we have published in our columns on several occasions the valuable results obtained by the means of Mr. Coxwell's balloon ascents, we insert with great pleasure the following appeal to the scientific world, to aid the intrepid aeronaut to resume his aerial researches, his balloon having been destroyed by a mob at Leicester:—The loss of Mr. Coxwell's new balloon, at Leicester, has excited in the public mind feelings of general sympathy. This magnificent balloon had just been built by Mr. Coxwell entirely at his own expense, and was designed by him to continue and extend the aerial researches so ably conducted by Mr. Glashier, on behalf of the British Association. Mr. Coxwell's friends and admirers feel that the public, as well as scientific men, have so great an interest in his being placed in a position immediately to resume his professional duties, that they have determined he shall not be left to his own unaided resources in the present emergency. With this view, a committee has been formed as under, and a banking account has been opened, entitled "The Coxwell Balloon Fund," in aid of which contributions are now invited from the public. The committee consist of James Glaisher, Esq., F.R.S., Royal Observatory, Greenwich, Chairman; H. Emerson Westcar, Esq., Royal Horse Guards; F. G. Burnaby, Royal Horse Guards; Captain Woodgate, Norwood; Lieutenant Hatton Turner, Rifle Brigade; Count Schaffgotsch, Berlin; Frederick Norris, Esq., King-street, St. James's; W. F. Ingelow, Esq., Holland-street, Kensington; Edward Atkinson, Esq., 5, Hanover-street, Regent-street; Fredk. W. Ellis, Esq., Maida-hill; J. W. Robins, Esq., Stamford-hill; S. W. Silver, Esq., Norwood-lodge, Streatham; Osborn Stock, Esq., Torrington-square; H. Thompson, Esq., Gresham-house (with power to add to their number). Bankers—The National Bank: Head Office, 13, Old Broad-street, E.C. Branches: 47, Charing-cross; 19, Gloucester-gardens, Bayswater; 112, High-street, Camden Town; 4, Arabella-row, Pimlico. All subscriptions will be duly advertised.

EXCURSION.—On the 9th instant the annual festival of the establishment at which this journal is printed and published took place. The company, after a delightful journey on the North Kent Railway to Northfleet, alighted, and after a pleasant walk through waving fields of corn and luxuriant hop-gardens, arrived at the charming and rural village of Swanscoombe, in Kent; for the selection of such a favourable place for a day of recreation and pleasure great credit is due to the indefatigable and obliging stewards of the day, Messrs. Gill & Butler. The morning was most agreeably spent in healthy and athletic exercises, such as cricketing, quoiting, running, &c.; the races were contested with much spirit—the first, of 440 yards, being won by Mr. Hill; the 100 yards race cleverly by Mr. Stocks; and the 200 yards race by Mr. Lees, after which the company—over sixty in number—sat down to a substantial repast at the Blue Anchor tavern, towards which the firm contributed most liberally. The chair was occupied by Mr. Cornell, sen., of the printing department, the vice-chairmen being Messrs. McFee, Freeman, and Bowden, representing various departments of the establishment. After the usual loyal toasts had been proposed in eloquent and appropriate terms, the chairman followed with that of "The Firm"—Messrs. Truscott, Son, & Simmons—which was received with hearty cheers and applause. "The Ladies" and "The Press" followed, the former being responded to in effective language by Mr. Beale and the latter by the editor of this journal. Several excellent songs were sung during the evening, and after spending a most interesting and agreeable day, the company returned to town at an early hour.

THE INDUSTRIAL COMPANY OF CENTRAL ITALY.—Amongst the numerous projects of the day, a company which has in view the development of the resources of Italy cannot be but favourably received. The direction of the above company appears to us to consist of gentlemen of high position in the commercial world, and the undertaking, under proper management, must prove as remunerative as similar enterprises have proved to be at home.

TO CORRESPONDENTS.

WILLOUGHBY SMITH.—The query addressed to us respecting the "Electro Tell-tale" will be answered.

L. S. M.—The publication you refer to is, we believe, defunct, in despite of its medico-galvanic proclivities.

A STUDENT.—The first volume is now ready, and may be had of the publishers, price 8s. bound.

SENEX.—A gentleman well known in the telegraphic world has accepted an invitation to become a candidate for representing an important borough in Parliament on the termination of the present session.

As information respecting Improvements, Extension of Lines, and Progress of New Undertakings will at all times be most acceptable, we hope that our readers will kindly render us assistance, by furnishing us with brief notices of events and occurrences in connection with electrical and scientific progress.

Communications intended for publication must be authenticated by the names and addresses of the writers; not necessarily for insertion.

Letters relating to Advertisements are to be addressed to the Publishers. All other letters and communications to be addressed to the Editor of the *Telegraphic Journal*, 4 & 5, Suffolk-lane, Cannon-street, London, E.C.

The *Telegraphic Journal* can be had of Messrs. SMITH & CO., Strand; J. ONWHYN, Catherine-street, Strand; Messrs. DAWSON & Co, Cannon-street, E.C.; Messrs. KENT & Co, Paternoster-row, London. Messrs. HEYWOOD & Co., Manchester; at the various railway stations; and of all news-agents, &c., &c.; or it can be supplied, if preferred, direct from the Office on the following terms:—

Quarterly, 4s. 4d. | Half-yearly, 8s. 8d. | Yearly, 17s. 4d.

TO ADVERTISERS.

The *Telegraphic Journal* is the most effective medium for inventors, patentees, contractors, manufacturers of insulating materials and electrical apparatus to submit their various specialities to the consideration of secretaries and managers of telegraph or railway companies, and other persons engaged in electrical and telegraphic pursuits.

Clerks, assistants, manipulators, and instrument makers, seeking employment, &c., will find the *Telegraphic Journal* a ready means of making known their requirements.

Advertisements must be delivered to ensure insertion before SEVEN O'CLOCK on Thursday evening in each week. The charges for Advertisements are:—

	£. s. d.		£. s. d.
Whole page	4 4 0	Quarter page	1 7 6
Half ditto	2 10 0	Four lines and under (single col.)	0 3 6

Single Advertisements from the country must be accompanied with stamps in payment.

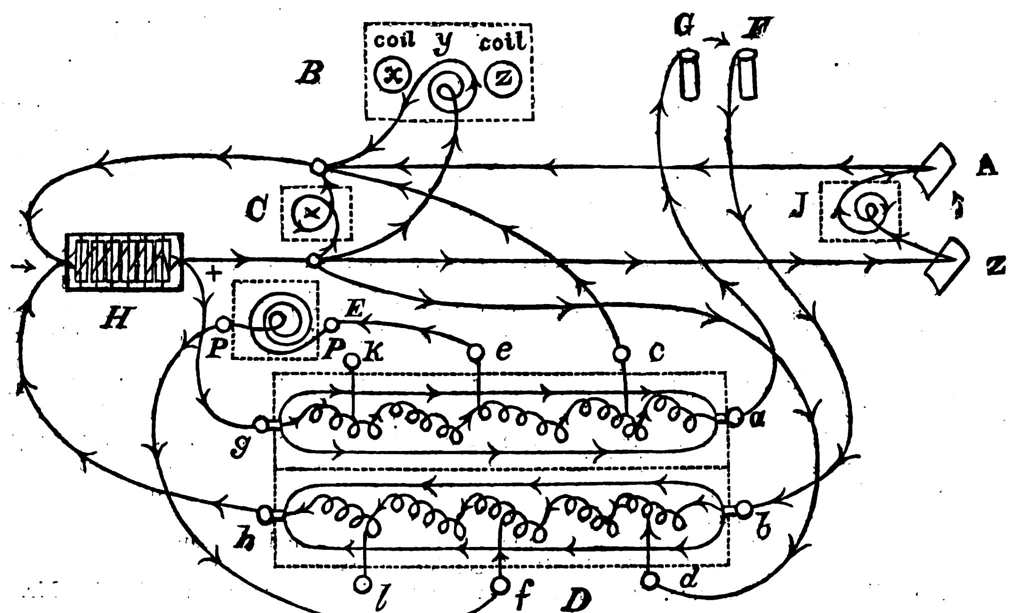
TELEGRAPHY WITHOUT CONDUCTING WIRES.

COMMUNICATED BY B. M.

I SUPPOSE, that many other persons besides myself have been anxiously looking for the publication of this patent; but till this week I have not had time to look into it. I really cannot say that Mr. Haworth's method of communicating signals is at all made patent to me, at least, and perhaps there are other dullards besides myself. When I first heard of it, I said, "Well, it is hard to say what is possible, and what is not; but at any rate this telegraphing without a distinct circuit must be by virtue of some law of electric conduction, or induction, or of both, hitherto unknown, if it is to be done at all;" for it appeared to me, that by no known law could it be done. Hitherto it has been found necessary, that half of the circuit at least must be insulated from the earth, when the earth is used as the other half: and generally, one half of any circuit must be insulated from the other half, and both from the earth, else your battery will be put on short circuit at the nearest point of non-insulation. Well, I thought, at least Mr. Haworth will show in his specification the *raison d'etre* of his system, and that will be something. I recollect, that about fifteen, or twenty years ago, we were going to have something similar done. That was really a recondite affair; but then there was a reason given for the method proposed. It was called "The Sympathetic Snail Telegraph." This was the pretended law of nature, on which it was based. That snails are wonderfully sympathetic: so much so, that if you bring snail A in contact with snail B for a short time, and then remove B, say, to the antipodes, and keep A here, if snail A's horn be tickled with a straw, B will draw in his horns at the antipodes: that is, providing he had them out; the author did not explain what would occur if he had not. Now here is the enunciation of a law of snail-sympathy at any rate, which no one can, or ought to contradict, but those who have proved that it is not so: and I am sure, I have not. After this law is settled, and fixed on a firm basis, all the rest is quite simple.

Take two boxes, each having twenty-six compartments, and in each compartment put a snail, first having marked each compartment with a letter of the alphabet, that is from A to Z in each box. Then bring snail A in one box, in contact with snail A in the other, and snail B with B, and so on to Z, and your telegraph instruments are complete. Now, if you take your box to New Zealand, and if I want to communicate with you, I take my straw in hand, and tickle my telegram out, which you will read in contortions, in your box, in New Zealand. Do you smile at the absurdity? Well, well, you will have a face as straight as a board before you have digested Mr. Haworth's system, or found the law, quasi, or other, on which it is based. I have had some hard work with it, and I mean you to have a little too; but I dare say the result will be the same with you as with me, namely, your labour for your pains. One thing I could do, and have done; that is, trace out the flow of the currents as laid down by Mr. Haworth, in his specification. This is a sketch of them, carefully taken from the abundant drawings and letter-press:—



H is the battery. C is a needle instrument, which is placed upon a box, B, in which are three coils, x, y, and z. The coils, x and z, have no connection with anything at all but the outside of the wooden reel. The coil, x, is thin ordinary insulated copper wire, coiled in the ordinary way, but apparently not for any use; the coil, z, is half filled with single insulated iron wire, and the other half with the same kind of wire, but double, and wound in an opposite direction; none of the ends have any connection with anything: it would puzzle Mr. Haworth even to tell of what use these can be. The coil, y, is connected with the other apparatus. We will go through the connections after we have described each part.

J is a box containing one coil. A is a copper plate, and Z is a zinc plate. Each plate is bent, and the convex sides are

turned in the direction in which the telegram is intended to be sent. The box, J, with its coil, and the two plates are buried in the earth. E is a box containing two coils. Each coil is wound with double wire, one wire in each coil is insulated, and the other is not. The four ends of one of the coils communicates with nothing; so I have left it out altogether, and the ends of the uninsulated wire of the other core has no connection with anything. The ends of the insulated wire are connected to the binding screws, P, P. The box, D, which the inventor calls the condenser, is divided into two compartments: each compartment contains a series of gutta-percha plates, wound round with insulated wire in one continuous length. The two series of flat coils are represented by the two series of spirals. The ends of the wires of each series are connected respectively to the binding screws, *g*, *a*, and *h*, *b*. Besides these end connections there are six others, four of them, however, only are used. The binding screws, *k*, *e*, *c*, and *l*, *f*, *d* are these connections, they are fixed in the sides of the box, and connected to the wires of the flat coils, in their passage through the box. Above and beneath these flat coils there are bands of stout gold foil, which are insulated from the coils and their four ends respectively are connected to the binding screws, *g*, *a*, and *h*, *b*, the same as the ends of the flat coils. Now in what way this represents a condenser, in any sense of the word, I have yet to find out. G and F are copper cylinders, sunk in the damp earth, and connected with binding screws, *a* and *b*, in box D.

Now for the connections. The instrument, C, is connected with the battery, H, and with the plates, A and Z, also with the ends of coil, *y*, in box, B; also with these are connected the binding screws, *c* and *d*, in box D. The ends of the coil in box J, are connected with plates A and Z; consequently with the battery, and preceding connections.

Again the battery, H, is connected with the binding screws, *g*, and *h*, in box D, and through them with the bands of gold foil, represented by the ovals in box D, and also with the flat coils in each respective compartment; these connections are continued through binding screws, *a* and *b*, in the same box, the copper cylinders, G and F. The binding screws, *p*, *p*, which are connected with the ends of the coil, in box E, are also connected with binding screws, *e* and *f*, in box D, and by their means with the internal flat coils. Binding screws, *k* and *l*, in box D have no external connection.

The inventor has not stated in what directions the currents flow; therefore we must be guided by what we find in the drawings and letterpress. The only thing we can find to guide us is the pair of buried plates, A and Z. These being a voltaic pair, the currents between them will flow from Z to A, through the damp earth. We will take this as indicating the general direction; but the circuits will be just the same whichever way we take the current as flowing. We will begin at the battery, at which there are two complete circuits, and these develope themselves into eight when the current is sent through C, and into six permanent ones when it is not. We will take the one through the instrument first, when the current is being sent through it. Then we shall have four complete circuits from this point—namely, through the instrument, through coil *y*, through the coil in J, and through the damp earth between the plates Z and A; the quantity flowing through each circuit, of course, depends on the balance of resistance. Commencing again at the battery, we have two complete permanent circuits, namely, through the coil in E, and through the damp earth between G and F; the two poles of the battery being permanently put to earth in the cylinders, G and F.

Besides these, there are two other complete circuits by means of the connection of the two systems. The ends of coil C, and coil *y*, are connected with binding screws, *c* and *d*, in box D, and by that means, when the current is on at C, there are two complete circuits with the battery, as will be seen by tracing the arrows. These make just eight complete circuits when the key is down at C. Then besides the two permanent circuits already referred to, there are four more, making six permanent circuits when the key is not down; namely, through the coil in E, and through G, F, also from binding screws, *c* and *d*, through instrument coil C, through coil *y*, through coil in J, and through Z A, making six permanent currents when the instrument is not in use. Now all these circuits are within the office, or within a few feet of it, and besides both poles of the battery are permanently put to earth in cylinders, G and F, only passing through a few feet of wire and a few inches of gold foil. Besides, when the key is down, there are four complete metallic circuits in the office, besides the coil of the instruments, which are open to the current, and one in J, buried in the earth; also the four earths, G F and A Z; but besides this, A and Z will have a current of their own, they being a voltaic pair.

Now, what will be the result of all this? Electricians, telegraphists, dilletantés! A sending of telegrams? And where to? To the mountains in the moon, or to the dog star? Will it not rather be the exhaustion of the Smee's battery in half-an-hour? And that is all. What is the use of Mr. Haworth giving himself all the trouble to invent and describe this wonderful apparatus? Would it not have been easier for him to have chalked himself a circle, and got into it with his wand and—*presto! presto?* The thing would have been done. But is Mr. Haworth in earnest? Not if his invention consists only in what is made patent. I do not know the gentleman; but I am told that he is a worthy man, and besides, it is my own opinion that he is a bit of a wag. I fancy I can see him with his thumb on his nose—of course not literally, but figuratively; no *gentleman* takes a sight physically; it is only the coster's who do that.

I have a theory about it, which makes it all clear; namely, that this gentleman is a partizan in the patent dispute, and after having sought out all the absurd patents he could find, he has thought to out-do them all, and so bring patents into utter ridicule and contempt. Still my theory may not be the right one after all; no man is infallible, and I least of all. For this gentleman says he has done it. He tells us what coils are effective to send a signal upwards of 400 miles. But how can these coils send a signal? They are not induction coils, but simply lengths of wire put on wood, and forming a complete metallic circuit, or circuits to the battery, in and about the office. They do not even terminate in the copper and zinc plates from which, he says, the signals take their departure; they merely touch them in their course, on their way through the box J: nevertheless, he has done it! There is no gainsaying that. But how? There is the rub. The specification of the patent does not make it clear, but rather makes confusion more confounded. The use of nothing is explained, the reason for nothing given; but certain instruments are described, and the connections laid down in the drawings and described in the letterpress, and we are told that this will do it; nay, that the thing has been done by it. I will not say that it must be by some new law, but that it is in direct contradiction to old laws already known these thirty years. But what can be said to the bare proposition that a current of electricity can be sent and returned at one and the same time through one and the same conductor, over 400 miles, aye, or even over a [illegible]? For really this is the question, this is what Mr. Haworth [illegible] to do, which he says he has done. He starts his curren[t] [illegible] one plate on its course of 400 miles, and receives it on its re[t]... on another plate, only a few feet away from the first, and gravely tells us this without even winking; when every[one] knows, who knows anything about the matter, that the cur[rent] will simply pass from plate to plate, taking the shortest co[urse] possible. All the absurd and contradictory apparatus descr[ibed] will be of no assistance, but the reverse; for they form [com]plete metallic circuits, which will each take its proportio[n]

the current according to its resistance, consequently the proportion of the electricity which will pass between the plates will be but small, and that will take the nearest course: so saith experience, else why so much trouble and expense to insulate line wires and cables? But Mr. Haworth says, nay. I wonder what Faraday, Joule, and all other electricians and telegraphists have been doing all their lives! Have they been babbling vain things that experience will not support, or talking common sense? How is it? I am bewildered, for Mr. Haworth has actually done it!

MALTA AND ALEXANDRIA TELEGRAPH.

No greater proof of the remunerative character of submarine telegraphy can be adduced than is to be found in the records of the Malta and Alexandria Telegraph. The statistics recently published by command of the House of Commons furnish us with material for comment, and show the rapid progress made, and the profitable business done, since the means of communication with Egypt and India have been available to the public. This line was laid by Messrs. Glass, Elliot, & Co., in the summer of 1861, but was not opened for traffic until the month of November in the same year. The government dispatches during the last two months of that year did not exceed 27; the number of local messages, 1,299; and the through telegrams, 1,615; yielding a revenue of £3,142 15s. In 1862 the traffic increased in a very remarkable degree. The total number of messages sent and received being 19,797, producing no less a sum than £38,380 7s.; or an average of nearly £2 per telegram. An account of the line and its working for 1863 is before us, and, certainly, its commercial success is very evident. The number of government dispatches has decreased on the previous year's working by 55; but the local and through messages have increased 50 per cent., yielding a proportionately augmented revenue. A few particulars concerning the construction of the cable may not prove uninteresting to our readers. The telegraph consists of a single conductor of No. 8 gauge, served with gutta-percha and Chatterton's compound, and encased in a sheathing of eighteen No. 11 iron wires. The cable is 1,535 statute miles in length, has a weight of 1.85 tons per statute mile, and is submerged in a maximum of 420 fathoms of water. Early in the present year an interruption occurred in the working of the line, owing to a ship's anchor having dragged and injured the cable. The damage was speedily made good and business resumed. On the formation of the Telegraph Construction and Maintenance Company, the lease of this line (held from government by Messrs. Glass, Elliot, & Co.) was transferred, and is likely to prove a very profitable acquisition to the Company, as the traffic this year to the present date exceeds the business of last year, by a considerable amount.

SAFETY FOR RAILWAY TRAVELLERS.

[FROM A CORRESPONDENT.]

Now that attention is directed to this subject with more than usual force, we have thought it advisable to make some suggestions that may lead to the economy of life and property, and the increase of railway dividends. Many accidents arise from passengers getting out of trains before they are properly and finally stationary. On arrival at its destination, a train is brought to gradually; but, as must be apparent to the thoughtful, the carriages being only connected by coupling chains, and kept apart by springs called "buffers," the hinder carriages must press in all their buffers, and so shorten the length of the entire train, before the weight of their impact can be overcome. It is between this period of the first pressing in of the separating springs and their after-expansion that the accidents prefer to occur. Standing with door in hand, the impatient traveller only waits till the train is nearly stationary, and then jumps out; but it may be that at that moment the "buffers" regain their power, expand themselves, lengthen the train, move the carriages, and send one or more of the feeble descending passengers under the wheels—to torture and to death.

We propose as a remedy a very simple arrangement. Under the door of each carriage let a pendulum be hung, with a small portion of it, terminated by a crown-shaped head-piece, projecting above the point of suspension. On this head-piece let there depend freely a projecting iron lip, passing under the carriage door, and being hinged inside the carriage, with a projection on its upper surface outside the carriage which will only allow the door to pass over it, and so to be thrown open, when the lip is depressed to its fullest extent. Immediately the train moves, the pendulums under each carriage oscillate, the amount of oscillation depending on the speed of travelling and the elevation of the pendulum weight. The head-piece to the pendulum top is so shaped as that the oscillating pendulum, in its deviations from the central line, raises the lip more and more, the lowest point of depression of the lip being when the pendulum is in the central line, or stationary. Then a sudden depression in the head-piece causes the lip to fall so low, that the door (supposing the lip to be held stationary in that position) would be able to pass over it. But the speed, number, and violence of the oscillations are too rapid for such a chance, and so the door is kept fastened till the pendulum ceases to oscillate. All danger will then be at end, because the few seconds needed to quiet the oscillations after the stoppage of the train will be amply sufficient to allow of the expansion of the buffers after the first impact of the carriages.

This is a cheap and simple arrangement. The pendulums could be easily added to any carriage without alteration of rolling stock, and locks would be thereby rendered unnecessary. Let the pendulums be placed on both sides of the carriages. It would be also easy to place them under the control of the "guard," and to affix close to them alarm bells, against which the pendulums should be made to strike at pleasure by mechanism or electricity. The oscillations might also be utilized most admirably for the keeping up of a telegraphic communication between each carriage of a train (if necessary) and the guard; and also to inform the passengers in each carriage of the name of the place arrived at, where and which of the carriages change passengers, the duration of stoppage, and the need for official assistance in any particular carriage.

Telegraphic communication in this great metropolis is in a backward condition, considering our requirements. Telegraphy of this kind might be introduced everywhere—in private house and business establishment—as a substitute for, and an aid to, letter-writing; but there is a want of connection, adhesion, and completeness, in the commercial appliances, and a need of public attention, somewhat unsatisfactory. Electricity, it has been proved, will increase the growth of our cereals—will retard the decomposing influences of disease, in many cases giving vitality and health—will, in fact, do anything which its thermal, sanative, and chemical character can accomplish. Let us for a few moments suppose ourselves tyros in the art. We can produce electricity by the contact of metals and liquids; can intensify the onward force of its created current by multiplication of the plate series; can multiply its volume by enlarging the surface of contact. All other arrangements are as but simple mechanism. Completing and interrupting the electric circuit will give us the initial power requisite to enable us to speak with lightning, on the wings of the wind. But like other inventions—though there are many ways in which to get up, continue, and intensify electrical forces—some are too expensive to make them commercially adoptable. Therefore, it is necessary to do as our gas companies—to give off such products in the manufacture as shall on their sale return the original outlay.

Along our highways the electric cords should be far more frequently used to give notice of fire, crime, storms, and of ordinary business concerns. Our postal system is yet imperfect. With the aid of electric telegraphy, and of pneumatic tubes, our letters might be despatched and delivered in a much shorter time, and with less fear of loss.

INTRODUCTION OF THE ELECTRIC TELEGRAPH.—How well I remember the ignorant wonder with which, travelling from Windsor to London by the Great Western, I looked upon the erection of tall posts at regular intervals along the line, and, in answer to the enquiry of a foreigner as to their use, told him I thought they were intended for gas lamps to light the railway. These mysterious standards were for the application of Mr. Cooke's patent for insulating the wires, which had been previously placed in iron tubes, buried beneath the ground.—*Charles Knight's Autobiography.*

REPORT OF THE LONDON DISTRICT TELEGRAPH COMPANY, LIMITED.

THE directors have much satisfaction in submitting to the shareholders the accompanying statement of accounts, showing that the income has now very nearly equalled the expenditure.

It may on the present occasion be satisfactory to recapitulate the half-yearly progress of the Company:—

Half-year ending.	No. of Messages.	Receipts for Messages. £ s. d.	Expenditure. £ s. d.	Deficiency. £ s. d.
June, 1860	26,115	550 19 11	2,282 10 7	1,326 2 4
December, 1860	47,365	1,058 19 2	3,294 0 6	2,168 1 7
June, 1861	64,785	2,137 1 7	4,394 12 3	2,177 11 4
December, 1861	77,939	2,592 15 10	4,663 5 4	1,995 13 7
June, 1862	123,280	3,956 4 8	5,077 17 11	1,077 15 4
December, 1862	124,222	3,999 3 2	4,958 4 2	894 0 4
June, 1863	129,710	4,216 6 11	4,721 1 3	440 9 4
December 1863	131,216	4,326 4 0	5,125 9 4	796 15 4
June, 1864	152,795	4,802 10 0	4,863 17 10	60 12 0

It will thus be seen that the increase in the income has been continuous and steady, whilst the expenditure appears to follow a fair average amount, and, it may be added, that the present rate has been found sufficient for transacting a remunerative amount of business.

From Parliamentary returns, recently issued, it appears that this Company shows the largest rate of increase in traffic of any of the existing telegraph companies.

During the past half-year the principal outlay on account of capital has been incurred in providing additional private telegraphs on remunerative terms, and in respect of the stations on the Metropolitan Railway, which were opened about the middle of the half-year, and which are worked by this Company, under an agreement with the railway company.

The general expenditure remains about the same. Under the charge for repairs and maintenance is included the renewal of the whole of the overhouse wires on the south side of the Thames, which were the first erected; and for renewing a portion of the wires in the south-west district.

The property continues in efficient working order, and by gradual repairs, as they become necessary, it is hoped that the present average expenditure in this respect will not be greatly exceeded.

BALANCE-SHEET OF THE COMPANY FOR THE HALF-YEAR ENDING 30TH JUNE, 1864.

We have examined the foregoing statements with the vouchers and the Company's books, and find the same correct.

19th July, 1864.

EDWD. SANDELL, ALFRED EAMES, } AUDITORS.

REPORT OF THE DIRECTORS OF THE MEDITERRANEAN EXTENSION TELEGRAPH COMPANY, LIMITED.

IT will be seen from the balance-sheet for the past half-year that the affairs of the Company are still prospering.

The aggregate revenue has slightly decreased as compared with the previous half-year, but this is owing to the second interruption which occurred on the Malta and Alexandria line; but as that line has now been restored through the exertions of the lessees, it may reasonably be expected that the traffic will steadily augment.

Respecting the increase which will be observed in the expenditure, the directors beg to explain that it is principally owing to the establishment of an English staff of clerks at Modica, in Sicily, for the improvement of the system of transmission of telegrams through Italy, inasmuch as serious delays and mutilation of messages were of daily occurrence, which rendered it imperative on the directors to adopt some means of removing that grievance.

The Company's cables continue in the same excellent condition.

The directors recommend the usual dividend—8 per cent. per annum—on the preference shares, and 4s. per share—equal to 4 per cent. per annum—on the original capital.

They also recommend the usual 10 per cent. on the gross earnings to be carried to the reserve fund.

158, Gresham House,
22nd July, 1864.

HENRY MOOR, Chairman.
HENRY C. ORTON, Secretary.

BALANCE-SHEET OF THE COMPANY FOR THE HALF-YEAR TO THE 30TH JUNE, 1864.

Dr.	£ s. d.	Cr. ASSETS.	£ s. d.

ABRIDGMENTS OF SPECIFICATIONS RELATING TO ELECTRICITY AND MAGNETISM, THEIR GENERATION AND APPLICATION.*

I.

THE indexes to patents are now so numerous and costly as to be placed beyond the reach of a large number of inventors and others, to whom they have become indispensable.

To obviate this difficulty, short abstracts or abridgments of the specification of patents under each head of invention have been prepared for publication separately, and so arranged as to form at once a chronological, subject-matter, reference, and alphabetical index to the class to which they relate.

The following rules have been adopted in deciding which specifications belong to this series of inventions.

1st. To include all specifications in which mention is made of electric or magnetic force as applicable in carrying out the invention.

2nd. To include all which depend on electric or magnetic science, whether such dependence is mentioned or not.

3rd. To exclude those in which no mention is made of their application to electric or magnetic purposes, although it may be somewhat evident that such application might be made. For instance, as in some specifications, no mention is distinctly and directly made of the application of gutta-percha to the coating or covering of wire for electrical purposes, it is not included in this series, although such an application of the invention is evident.

4th. To exclude all those in which no other allusion to electric or magnetic science is made than the word "galvanized," as applied in the ordinary process of zincing iron.

In all cases in which a reasonable doubt exists as to whether an invention is to be included in this series or not, the abridgment is included, and the cause of doubt stated.

In making the abridgments of specifications of mechanical applications of electricity and magnetism, the rule of tracing their operation from the prime mover to the result has been observed, when possible. A similar rule has been observed with reference to electro-chemical processes. The course of the electric current from one battery pole to the other, through the work to be done, has been traced in all cases in which such a method of treating the subject could tend to clearness of description. When the complicated nature of the subject requires it, each description is begun by a short summary of the whole action of the machine or process treated of.

* Printed by order of the Commissioners of Patents.

All the quotations from the printed specifications (included between quotation commas throughout the work) are given in the exact punctuation and orthography therein used; however, to draw attention to any passage more immediately connected with this series of abridgments, portions are sometimes italicised that appear in Roman type in the original.

Care has been taken to preserve correctness in the use of the scientific terms occurring in the work, a caution rendered necessary by the frequent misappropriation of terms by inventors. The word spiral, for instance, is frequently used instead of helix, isolate for insulate, aluminium (the French name) for aluminum, &c. &c. To avoid misunderstanding in regard to the meaning of terms which some patentees appear to consider synonymous or doubtful, the following definitions are given:—

Brake, an apparatus used to stop rotation, or other mechanical movement, by the friction of surfaces. (See *Practical Mechanic and Engineers' Magazine*, October, 1843, pp. 25-27, December, 1843, pp. 98, 99, and April, 1844, pp. 258, 259.)

Break, a commutator, or apparatus to interrupt or change the direction of electric currents. (See *De la Rive's Treatise on Electricity*. Vol. I., p. 377.)

Helix, a screw-form curve. A curve generated by winding an inclined plane round a right cylinder; this curve is necessarily not situated in one plane, as all its points lie on the surface of a cylinder, and therefore at equal perpendicular distances from the cylinder's axis, the said perpendicular uniformly increasing in height above the base of the cylinder. According to another definition, it is the curve formed by a straight line twisted round a cylinder, so that the perpendicular distance between each convolution is a constant quantity. It may also be defined as "the curve of double curvature formed by a thread, wrapped round the surface of the cylinder, so as always to make the same angle with the axis." This term is used to name the curve formed by the winding of the external protective wire round electric telegraph cables; it also applies to electro-dynamic coils, to springs that act by tension in the direction of their axes, and to other similar arrangements. (See *Encyclopædia Metropolitana*, Integral Calculus, Part III., pp. 143, 144; also *Library of Useful Knowledge*, Differential and Integral Calculus, pp. 396 and 415-417.)

Insulate, to separate, electrically speaking, or to surround with a non-conducting body; this term is used in reference to an electrified body which it is desired to preserve in that state. (See *Dr. Golding Bird's Natural Philosophy*, p. 162.)

Isolate, to separate or detach; this word has no express meaning in the electrical vocabulary. (See *Maunder's Treasury of Knowledge*, Dictionary in Part I.)

Pall, a click that falls by its own weight into the teeth of a toothed or ratchet wheel. (See *Practical Mechanic and Engineers' Magazine*, April, 1844, p. 251.)

Spiral, a curved line situated in one plane, and generated as follows:—A straight line of indefinite length moves round a fixed point and from a fixed line passing through the point; a point also moves along the moving line, starting from the centre or fixed point at the same time that the line commences its motion; the point will trace out a curve commencing from the centre and extending through a series of turnings gradually outwards, which curve is a spiral. It may also be defined as the curve formed by twisting a straight line round a fixed point, so that the distance between each convolution, radially, is a constant quantity. Mathematicians recognize several distinct kinds of spirals, each having its own characteristic properties. This term is used to name the springs that are in one plane, and act by unwinding a barrel, such as the main spring of clocks and watches, &c.; it is also applicable to flat electro-dynamic coils commenced upon a core and proceeding outwards by convolutions in one plane. (See *Library of Useful Knowledge*, Algebraical Geometry, pp. 193-195, Differential and Integral Calculus, pp. 356-358, and Practical Geometry, pp. 118, 119; also *Hind's Differential Calculus*, pp. 262-285; also *Encyclopædia Metropolitana*, Integral Calculus, Part III., pp. 136, 137.)

Berzelius' ammonium theory has been adhered to throughout the text of the work, and the best recognised names for chemical and metallic bodies, such as platin*um*, alumin*um*, ammoni*um*, have been adopted.

When two words are used as one adjective to qualify a noun, they are connected by a hyphen thus—"line-wire circuit," in contradistinction to "local circuit," &c.

In an appendix will be found the abridgments of eleven specifications omitted from the body of the work, but which are duly recorded in the indexes.

In the title and introductory part of these abridgments the word "generation" is employed as the equivalent of the various expressions, "producing," "exciting," "inducing," or "developing."

Under the word "electricity" is included statical, frictional, or tension electricity, steam electricity (or hydro-electricity), galvanic (or voltaic) electricity, thermo-electricity, magneto-electricity, that induced in electro-dynamic coils by secondary currents, or by their movement across the lines of magnetic force, that evolved from heated substances as tourmaline, talc, &c. (pyro-electricity), and from electric fish, as the torpedo, gymnotus electricus, &c., animal electricity, and other sources of less note.

Under the word "magnetism," that of permanent, induced, or electro-magnets, under whatever form they may be set forth, is included.

It is hoped that the publication of these abridgments will prevent the disappointment consequent on repatenting an old invention, and, by setting forth what has been already done in this department of practical science, enable inventors to exert their talents upon discoveries and applications at once new and practical.

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

THE Thirty-fourth Meeting of the British Association for the Advancement of Science will commence at Bath, on Wednesday, the 14th of September, 1864, under the Presidency of Sir Charles Lyell, M.A., LL.D., D.C.L., F.R.S., and the following are the arrangements for the meeting:—

The General Committee will meet on Wednesday, the 14th of September, at 1 p.m., for the election of sectional officers, and the despatch of business usually brought before that body. On this occasion there will be presented the report of the Council, embodying their proceedings during the past year. The General Committee will meet afterwards by adjournment. The first general meeting will be held on Wednesday, the 14th of September, at 8 p.m., when the President will deliver an address; the concluding meeting on Wednesday, the 21st of September, at 3 p.m., when the Association will be adjourned to its next place of meeting. At two evening meetings, which will take place at 8 p.m., discourses on certain branches of science will be delivered. There will also be other evening meetings, at which opportunity will be afforded for general conversation among the members. The Committees of Sections will meet daily, from Thursday, the 15th of September, to Wednesday, the 21st of September, inclusive, at 10 a.m. precisely. The Sections will meet daily, from Thursday, the 15th of September, to Tuesday, the 20th of September, inclusive, at 11 a.m. precisely. Reports on the progress of science, and of researches entrusted to individuals and committees, and other communications intended for presentation to the Sections, are expected to be forwarded in letters addressed to the Assistant-General Secretary, at Bath, previously to the meeting, accompanied by a statement whether the author will be present, and on what day, so that the business of the Sections may be satisfactorily arranged. The reports complete, and concise abstracts of other communications, are to be delivered to the Secretaries of the Sections before which they are read, previously to the close of the meeting, for publication in the Transaction. As the reports on Science may be interesting to more Sections than the one which originally called for them, it is desirable that the authors should be prepared to furnish the means of reading them in any other Section at the request of the President and Secretaries of that Section. The following are the titles of the Sections to which communications may be presented:—Section A. Mathematics and Physics. B. Chemistry and Mineralogy, including their applications to Agriculture and the Arts. C. Geology. D. Zoology and Botany, including Physiology. Sub-Sections D. E. Geography and Ethnology. F. Economic Science and Statistics. G. Mechanical Science.

At the first meeting of the General Committee it will be proposed by Dr. Hunt, "That Section E. shall include Geography, Ethnology, and Anthropology." An Index to the volumes of Reports of the British Association, from 1831 to 1861, is printed, and will be issued to those members who have subscribed for it, at 12*s*., carriage included.

TORPEDOES.—A correspondent of the *Scientific American* describes the manner in which the Confederates have introduced torpedoes to their enemy's vessels. It appears that a small screw propeller is employed to bear a message, under a flag of truce. At the head of this tug (a seemingly harmless vessel, being no more than twenty-five feet long), under water, is attached by ropes a torpedo. It is made of half-inch boiler iron, 33 inches outside diameter; length, 4 feet; cylindrical length, 22 inches; and contains 1,015 lbs. powder. This instrument is furnished with spikes and is connected with a galvanic battery by insulated wires. "In the affair of the attack on the Minnesota, after replying to the hail, the tug stopped a moment, then suddenly steamed under full headway, bow on, for the Minnesota, thrusting the torpedo forcibly against the ship, thereby causing the spikes to fasten themselves firmly in the timbers; then, on cutting the ropes, the tug was instantly detached from the torpedo, and backed rapidly to a safe distance, and the powder fired by means of the wire of a galvanic battery."

ARRANGEMENTS FOR METEOROLOGIC TELEGRAPHY.

IN a previous number of this journal we published an abstract of the report of the meteorologic office of the Board of Trade for 1864. This department was originated in 1854-5, and since that date a mass of valuable records has been obtained, classified, and published, under the direction of Admiral FitzRoy, to which we desire to direct attention. Before the establishment of the meteorologic office the data of meteorology were scattered, and in a state unavailable for observation and comparison—so essential in the reduction of phenomena to principles and uses. These have been brought to order, and a science has been evolved the importance of which to the mercantile marine can hardly be estimated. Professor Dové says, "The problems of the atmosphere are too complicated to allow of their solution off hand," yet within the brief space of ten years a system has been instituted whereby meteorological variations, &c., are communicated to, and received from, nearly all the coasting stations of the United Kingdom and the Continent. One result of these arrangements has been an immense saving of human life and valuable property. In order to extend the usefulness of this department application was recently made to the House of Commons for an increase of the annual grant allowed by the Treasury for meteorologic purposes. Exception was taken to the vote, but we are glad to find that the intelligence of the House of Commons prevailed over the peurile objections urged against the labours of Admiral FitzRoy, and that a grant of £7,900 was voted by a large majority. In the report above referred to the author says: "I submit that our knowledge of atmospheric changes and their indications is already sufficient for practical purposes, and may be communicated to a fairly educated person." We can, therefore, attribute the opposition to but one reason, which will be sufficiently obvious.

The following directions have been furnished to the various seaports and elsewhere, which will show the exactitude required, and care bestowed in making observations, and in the arrangements for meteorologic telegraphy; and will also enable many of our readers to understand the arbitrary signs (rendered necessary by limited space) in the daily weather bulletins emanating from the meteorologic office of the Board of Trade :—

Two barometers should be suspended indoors, so that one may be a check on the other. The distinguishing number of whichever is used, and its estimated height above high water, should be made known, by telegraph, the first day; and occasionally afterwards, when requisite. Knowing here your tidal peculiarities—elevation above mean sea level is obtained.

Two thermometers should be fixed outside the house, at the north side, and a third near them, with its bulb wet, or, rather, moistened.

Once a day, at about eight in the morning, the rainfall (R), the highest or lowest extreme of the mercury in the barometer, and in the exposed thermometer (T), since last report (as nearly as can be ascertained by the reporter), the reading of one barometer (B), and its attached thermometer—the character of the weather since the last report; the reading of the exposed dry thermometer, the difference always less—of the moistened thermometer; the direction of the wind at that time (W), its estimated force (F), the character of the weather at that time (I), and the state of the sea (S—sea-disturbance); should be telegraphed to the meteorologic office, in accordance wth the following explanations.

Each telegram will usually consist of five or six groups of figures (each group containing five figures), and perhaps a few words or letters.

No alterations or reductions are to be made by the observer, who will transmit them as "read off" (except in a few special cases).

Rainfall, Snow, or Hail (if any).

The first group will be "rainfall" (R), omitting decimal points between or before figures.

With each morning report, when rain enough has fallen to be measurable, its duration, in hours, from 1 to 24 (or to 48, after Sunday or a holiday), should be in the two first places of a group, or word, of five figures; a cypher being before 1 to 9. Quantity of rain, &c., should be shown by the three last figures of five as inches and two places of decimals. Thus, if rain had prevailed about eight hours since last report, and an inch and a-half of water was in the gauge, the group should be 08150; if thirteen hours, with two inches and five hundredths, the group should be 13205; if three hours and thirteen hundredths, then 03013.

Highest or Lowest Extreme.

The second group will show the highest or lowest extreme (the most remarkable) of the mercury in barometer (B), and in exposed dry thermometer (T), since last report by telegraph, whether recent or otherwise.

B will have the three first places for last integer and two first decimals; T will have the two last figures for degrees (only) of exposed dry thermometer. Thus, supposing $B = 30.142$ and $T = 59$, the telegraphic group should be 01459; or if $B = 30.147$ and $T = 59.8$, it should be 01560 (7 and also 8 being more than one half).

Barometer (B).

The third group will be the height of the barometer (B), read to two places of decimals, but omitting first figure, and points—but adding two figures for the temperature of the attached thermometer, to degrees only; thus, 90462.

The fourth group should express the extreme, not general character of wind and weather (W, F, I) only, since the last report, or during the whole time elapsed since the last hour of reporting (as far as can be ascertained by the reporter).

The first two figures will show direction of wind (W); the third and fourth figures, force (F); and the last figure, character (I). Thus, supposing $W = 10$, $F = 6$, and $I = 7$ (rain), the telegraphic group should be 10067.

Thermometer (T) and Difference with Direction of Wind (W).

In the fifth group the first three figures will show the reading of the exposed thermometer (T) and its difference above the moistened one; and the two last figures the direction of the wind (W) given by the true meridian (by the sun or pole star, by a chart, or by the world).

The direction of the wind will always be given in figures—1 to 32—North being 32, East 8, South 16, West 24, and so, proportionally, for the intermediate points, a cypher being placed before the figure indicating the direction when less than 10, (= N. by E. to E. by S.) Thus, supposing $T = 54$, diff. $= 3$, and $W = 8$, the telegraphic word will be 54308.

Force of Wind (F).

In the sixth group the first two figures will show the estimated force of the wind (F) from 1 to 12, supposing 1 to represent the lightest breeze, and 12 a hurricane (a cypher being placed before the figure indicating force when it is less than 10).

Amount of Cloud (C).

The third figure gives the estimated amount of cloud (C) from 1 to 9.

Character of Weather—Initial (I).

The fourth figure indicates the character of the weather (I), according to the abridged "Beaufort scale."

Sea Disturbance (S).

And the fifth figure the amount of "sea disturbance" (S), from 1 to 9. Thus, supposing $F = 2$, $C = 3$, $I = 1$, and $S = 4$, the telegraphic word would be 02314.

No decimal points should be noted in the telegrams. Using the method just described, they are unnecessary: while each decimal point might be counted as a word or figure, and thus increase expense.

Five figures should be placed invariably for each word, cyphers being used to keep the figures in their proper relative places; the cypher being very carefully placed, and always before the unit, or other cypher, to which it refers, when used for this purpose.

Special occasional information, when necessary, should be transmitted in the common manner by actual words, in addition to the above described groups; but abbreviations should be made, by substituting such letters for words as are used in the scales to which reference is made in these directions.

No regular meteorologic telegram is required to be forwarded on Sundays or official holidays, but one reading of instruments, and a regular notice of the previous weather, &c., should be taken on such occasions, and recorded, with other daily ordinary observations, in a regular form, which should be sent by next post.

It will be understood that telegrams should be despatched from their starting points (if practicable) at eight o'clock in the morning, and from selected special stations at two in the afternoon. To effect this the observations should be made, and the summaries of recent weather well considered, before those hours arrive. The slight changes that may occur, in about a quarter of an hour, are of little importance compared with the real advantage to the public of early and sufficiently precise information.

Reporters should send extra telegrams, at times, on their own responsibility, when the barometer is falling much or rapidly; say, having fallen nearly one-tenth of an inch, hourly, for more than two hours, since the last weather report was sent to London.

All telegrams, from all stations, should have five or six groups of figures in the morning; but in the afternoon, from the special stations, fewer may be transmitted.

It should be clearly understood that the first and second groups of figures refer to the whole interval of time, whether only a few hours, or one or two days and nights—as from Saturday to Monday—elapsed since the last official telegram, whether a regular or an extra report.

The reports of weather just recently prevailing, and the extreme ranges between the last two transmitted records, are very valuable; and it is earnestly hoped that not only individual abilities and judgment will be exercised, but also that conclusions may be drawn from the opinions of others, especially seafaring persons, shepherds, fishermen, gardeners, or agriculturists.

When reports are delayed beyond such a time as would enable them to be published in their proper order, they should be sent by the next post: not by telegraph, as in such cases they can be used only for record, and subsequent inter-comparison.

Although reporters are not on duty beyond a certain time of the day, it is hoped that general, and occasionally special information will be obtained by them from other persons, which may much enhance the value of their communications, and will be duly estimated in future arrangements, as well as in recommendations to favourable consideration.

RAIN AND FOG.

Portable rain gauges should be placed on the ground, or in any position exposed to a free fall of rain, snow, or hail, where neither buildings, nor walls, nor trees shelter or cause eddies of wind. They should be supported by a frame, or other means, admitting of their being emptied daily, but preventing their being blown down.

Generally, on or near the ground is preferable to an artificial elevation; but, if so raised, height above ground should be registered and officially reported.

From day to day, in the morning, the quantity of water from rain, snow, or hail (melted) should be measured very carefully and recorded.

It is not expected that exact duration of rain, snow, hail, or fog can be usually registered, but very near approximations may be made by collecting the notices of various persons. When fog continues for an hour or more, its duration and character should be registered and telegraphed with the next usual morning report, thus, "Five hours of very thick fog till seven p.m.," or, "Three hours of light fog still continuing," &c.

The measuring glass or tube should be used with great care. The gauge should not be opened oftener than once a day (except on occasions of heavy rain, thick snow, or much hail, in a comparatively short time).

The glass tube (supplied in duplicate) is graduated to inches and decimals. The marks are fixed by actual trial, and comparison with another kind of rain gauge duly verified. They are artificial inches. This tube should be placed upright in the gauge, with its upper end open; then a thumb or finger pressed on the upper aperture, while the tube is lifted gently out, holding in the lower part a small quantity of water, the upper edge of which is at the mark to be read off, and registered. Smaller decimals of an inch may be estimated by eye. The rain gauge should then be completely emptied and carefully refixed.

CAUTIONARY OR STORM-WARNING SIGNALS.

A staff and two canvas shapes being provided, the following use may be made of them occasionally; perhaps once or twice in a month on a yearly average.

One shape, that of a drum, or cylinder, has the appearance of a black square of not less than three feet, seen from any point of view, when suspended.

The other shape, a cone (not less than) three feet high, appears triangular (from any point of view) when suspended.

A cone, with the point upwards, shows that a gale is probable; at first from the northward. NORTH CONE.

A cone, with the point downwards, shows that a gale is probable; at first from the southward. SOUTH CONE.

A DRUM alone shows that stormy winds may be expected from more than one quarter, successively.

A cone and drum give warning of dangerous winds, the probable first direction being shown by the position of the cone—point up, above the drum for northerly, or polar wind, W.N.W. by the north to E.S.E.; point down, and below the drum, for southerly, or tropical E.S.E. by the south, to W.N.W.

A conspicuous place should be selected for signalling, near the telegraph station, whence other places may repeat the signal, or be warned; and, if practicable, the signal staff or pole should be in view of seafaring persons, besides the nearest coast-guard station.

When both these objects cannot be attained without too great distance from the telegraph station, one only—that of visibility to some of the seafaring community—should be secured; and in this case a message should be sent to the nearest coast-guard.

Whenever such a signal is shown, in consequence of a telegram from London, it should be kept up distinctly till dusk of that day only, unless otherwise specially directed.

These cautionary signals advert to winds during some part of the next night and two or three days; therefore due vigilance should prevail until the weather is again settled, but without deferring departures or any other operations unnecessarily.

More extended notice may be given by local interests and authorities, as London can only warn principal outports. The coast-guard will repeat the warning as far as means allow, and extension of such cautionary notices can be effected by private assistance along the most frequented shores, where alone they are required.

When a cautionary telegram is received at any place after four o'clock p.m., it should be followed by a Night Signal, which should be hoisted at dusk, and kept up till about nine o'clock, or even later, till toward midnight.

NIGHT SIGNALS.

Three or four signal lanterns are intended to be hoisted, as shown in the following diagram.

They should be kept up from dusk, or the time of receiving a warning telegram, until late the same evening; even till near midnight, if thought advisable on the spot, but not after that time.

A person should be employed to clean, trim, hoist, keep alight, take care of, and return these signal lanterns, for which service payment for each night of actual use will be made. This payment is intended to be an average, whether three or four lanterns are hoisted, and for whatever time shown lighted.

Spreaders, or yards, not less than four or five feet long, should be provided at each station, with good durable rope fittings.

Larger signal shapes, and better lanterns, masts with yards, and greater distances between the lights of a signal, would be desirable—though at present too expensive for general establishment.

Telegrams will not be sent on Sundays, except on emergencies (seldom occurring), and then, of course, only to those stations open at the time; but as vigilance will always prevail, by night as well as by day, on the part of the meteorologic office, no extensive change of weather, or generally dangerous atmospheric commotion ought to be unforeseen, nor should delay occur at any time in telegraphing to the coasts threatened, since attempting to prevent unnecessary risk of human life is the important object of these measures.

It should be remembered that only the greater and more general disturbances of the atmosphere can be made known by this method, not merely local or sudden changes which are not felt at a certain distance, and do not therefore affect other localities. Local changes should be indicated to observers at such places by their own instruments—by signs of the weather—and by due attention to the published weather reports.

Much inequality of atmospheric pressure (tension), or temperature, great fall or rise of the barometer, sudden or rapid alterations, great falls of rain or snow, foretell more or less strong wind, with its usual accompaniments, either in some places only, or throughout an extensive area of hundreds, if not thousands of miles; some tracts, however, remaining almost unaffected, unless by rain or squalls.

Speaking generally, there is less occasion to give warning of southerly gales, by signals, than of northerly, because those from the southward are commonly preceded by notable signs of the atmosphere, such as a falling barometer, and a temperature higher than usual at the season; whereas, on the contrary, dangerous storms from a polar quarter—north-west to north and easterly—are sometimes sudden, and preceded by a rising barometer, which may mislead persons, especially if accompanied by a temporary lull of a day or two, with a fallacious appearance of fine weather. This fallacy is caused by a circuitous movement of wind following—influencing by checking and then overpowering, or uniting with—a preceding similar sweep.

Occasionally, however, a southerly gale begins with a high barometer, and only as it increases does the glass fall. This occurs when the mercury has fallen notably in the north, and is still falling there.

Southerly gales in the Channel, and on our south-westerly coasts, are often, if not generally accompanied by northerly or easterly winds on the east coasts of Scotland, which at times affect England also on the north-east. Between these opposite winds (which are parts of circuits) more or less space, with variable light, or squally winds, occurs; and as such areas are uncertain, according to localities and extents of circuits, they should be included in cautionary notices, although at times it may be seemingly without occasion.

When a gale occurs with a high barometer, which does not fall, but remains steady, or rises, a northerly (polar) wind, or a duration of fine weather, may be expected, and more of either as the delay of approach is greater.

These signals are intended to be cautionary, however otherwise called. Limits of space and time are not assignable to winds so accurately as to warrant exact definitions for specific places. Only general terms, and districts, or coasts, are expressed, within which margins individual judgment may be fairly called into exercise.

While giving notice of considerable atmospheric disturbance over a part, or the whole of the British Islands, these signals are not intended to interfere with local knowledge, or to be in any degree compulsory.

(To be continued.)

THE PERSIAN GULF TELEGRAPH.

(Continued from page 20.)

The ships all arrived at Gwador by the 29th of January, when they were met by the Victoria, Captain Arnot, and the Clyde (gunboat), Captain Hewitt. The Kirkham's cable had to be laid first, as she had on board the shore end, 6·37 miles in length. After a careful survey of the bay, it was found that the Kirkham could not approach within three miles of the beach. It was, therefore, determined to pay out as much from the gunboat Clyde as her draft of water would permit, and lay the rest as usual from boats. The gunboat was, therefore, prepared for this operation by the removal of her heavy gun amidships, and filled with a portion of the Marian Moore's break, called the holding back sheave, which consists of a large V sheave, having a break attached to it. The cable passes over this sheave, and is made to grip in the sheave by a small weighted pulley resting on it (termed commonly a jockey pulley). Thus, when the break is applied it checks the passage of the cable. This sheave is used on board the ships to make the cable lead tightly on to the large drum behind which it is fixed, in the same way that a man, when easing a rope round a bollard, holds on to make the

turns bite. This machine has never before been employed as a break by itself alone, and its adoption was necessitated by the long length of cable which had to be laid in five fathoms of water from a ship that was too small for the reception of the regular break. The usual plan adopted in landing shore ends is to check it by hemp hand stoppers, which are imperfect in their action, besides being quickly worn out when the distance is so great. Judging from the admirable manner in which it answered, this, or a modification of the same, will be used in laying shore ends in future.

Two miles of shore ends were coiled on the deck of the gunboat, and upwards of half a mile in each of the Zenobia's paddle-box boats. The Kirkham, Clyde, and paddle-box boats were then towed to a buoy, placed as near the shore as the Kirkham could approach, and the latter having anchored, the cable was payed out from the Clyde towards the shore, and afterwards that from the paddle-box boats. The end being landed, and the cable carefully tested by Mr. Laws, the electrician to the expedition, and his assistant, Mr. Lambert, the operation of paying out commenced at about eight p.m. of the 4th of February. All the hands in the cable ships, consisting of a number of experienced hands from England, and a number of old hands late of the Bombay marine, were told off in two watches to their various stations. These stations consisted—firstly, of the cable men in the hold to clear away the wood packing, &c.; secondly, of the ringmen on the lower deck to lower and adjust the rings, &c.; thirdly, of the men stationed from the hatchway along the bridge to the poop, to pass the word from the lower deck or hold to the poop; fourthly, of the breaksmen and their assistants, and besides these, the signalmen on the forecastle, the logmen, and lamp trimmers, and various quartermasters and messengers.

Each of these separate departments had a leading hand in charge, besides a general foreman of the whole, who reported, at the beginning of his watch, and afterwards from time to time, to the engineer on duty, as to whether each man was at his post, and all going well above and below deck. No shouting, or even loud speaking, was allowed on any account. The ship's officers had to restrain the usual tendency of sailors to make themselves heard from the poop to the foretop, and, indeed, special precautions had to be taken to prevent, during the heaving of the common log, the cry of "Stop" when the glass is run out, and which in a ship when a cable is running out at the rate of 6½ knots an hour, has rather an alarming effect in the middle of the night to those who are anxious or have delicate nerves.

All the machinery worked smoothly, and, as the cable was confined and guided by fair leaders and guides in the most perfect manner from the hold to the breaks, so as to prevent it effectually from jumping and swaying about, it ran itself overboard in the most docile manner, and in respectful silence, while, there being no ship's engines to clink and clack, another cause of noise was, in this case, eliminated, and the total absence of the usual noise in paying out a cable was really remarkable, the silence at times being such that the fall of a pin could have been heard.

Of course, as the motive power was not in the cable ship, it would have been impossible to stop so suddenly as in a steamer, where the engines can be reversed, and it was in consequence of this that every precaution was taken in designing the machinery and arrangements to prevent the possibility of requiring such a sudden stoppage, and, indeed, except to change from hold to hold, no such necessity for stopping at all during the laying of any of the separate lengths ever occurred.

It was only common prudence, however, to have at hand the means of communicating quickly from the cable ship to the towing vessel as to easing, and stopping, and going on. This was done in the daytime by three small hand flags, white meaning "go on," or "all right;" blue, "ease her;" and red, "stop her!" At night a white, green, or red light was used instead of the flags. One of these signals was constantly displayed on the forecastle of the cable ship, and a similar one on the taffrail of the Zenobia showed the signal was seen and understood.

It was further very desirable to have the means of communicating freely between the cable ship and towing ship as to the course, tides, soundings, rate, and as well as to give special instructions from the cable ship to the towing ship when the end was about to be buoyed, which occurred on two occasions during the laying of the Gwador and Kurrachee section. To have attempted to do this by the old cumbersome means of flags or lanthorns would, it was felt, have been utterly useless.

The system of representing the dots and dashes of the Morse telegraphic alphabet in the day by a rough piece of mechanism, which allowed of a white dot being shown suddenly on a black board, and kept there for any required period, and at night by means of a light enclosed in a box, with the means of eclipsing or showing it at pleasure, was, therefore, experimented on between the Marian Moore and the Semiramis when on their passage from Bombay to Gwador, and found to answer so admirably that it was thenceforth adopted as the general means of speaking from one vessel to the other throughout the whole expedition. At first it was only used between the cable and towing ships, but the naval officers soon saw the value of the system, and were enchanted with it, and each began in the most persevering way to study the Morse alphabet. As several officers succeeded in learning to "read" and "send" very creditably, it was used as a general means of communicating between the ships when at anchor, and, indeed, when the Zenobia, Assaye, Amberwitch, and Scinde were laying in Gwador Bay before laying the Gwador and Kurrachee section, lights might be seen flashing away from three of the ships at a time.

The saving of time and labour to boats and boats' crews is sufficient alone to recommend the system to general use at sea.

With regard to the navy, it would, of course, be invaluable; but true to their principles, it is not likely that that very cautious Conservative body, the Lords of the Admiralty, will adopt it until it has been at least ten years in use by the mercantile marine, Lloyds, &c.

But, although there is not much hope of its being formally introduced by the Admiralty into the royal navy, there is some chance of its being brought in a less formal manner to the notice of naval officers generally, as Commander Bradshaw, R.N. (commander of H.M.S. Severn), who accompanied the expedition as principal surveyor, has learnt to "send" perfectly, and has flashed many a joke from the Zenobia to his friends in the cable ships.

(To be continued.)

SONG OF THE ELECTRIC TELEGRAPH.

BY E. L. BLANCHARD.

Away where the sunlight is bright'ning,
Away where its last beams expire,
I speed with the flash of the lightning,
I fly on the wings of the wire!
By me are earth's barriers riven,
By me are its boundaries spread;
A word, and the impulse is given;
A touch, and the mission has sped!
Hurrah! 'tis the best conjuration
That Science, the wizard, has done!
Through me nation speaks unto nation,
Till all are united in one.

In silence I stealthily travel,
Unseen, and unread, and unheard,
For not till my agents unravel
My secret is whisper'd a word.
Through darkness and daylight, unheeding,
Alike on my errand I go,
To deep-throbbing hearts ever speeding
My tidings of gladness or woe.

What matter the theme or the distance?
All heed what my messenger brings;
To Commerce I lend my assistance,
For Cupid I quicken his wings,
Now thwarting some runaway wooing,
I cling to the fugitives' track;
And now with Law's vengeance pursuing
I bring the pale criminal back.

Ere the voice of the echo had spoken,
Ere thought could recoil from its birth,
If the links of my path were unbroken,
My flight would encompass the earth;
From the bright star that gleams far above us,
Flashed onward through measureless spaec,
A welcome from voices that love us,
My own in a second would trace.

Oh! would that some kindred communion
To man we could hope to impart,
That a bond of such magical union
Might link every heart unto heart!
Not a tear that we now seek to smother
Would then fall alone or uncared,
Not a joy, but the heart of another
Would thrill with the bliss that it shared.

We need not, should fate give denial,
This fanciful dream wholly spurn;
Let sympathy touch but the dial,
A chord shall be struck in return.
No wish need be kept unimparted,
Or lost as on selfishness thrown,
But each from the heart as it darted
Would find a response in our own.
Oh! let love take the world and prepare it,
As swift to respond as receive;
Let us hear but of sorrow to share it,
And know but the want to relieve!

BENJAMIN FRANKLIN'S LABOURS.—Mr. Parton, an American writer (and the husband of "Fanny Fern"), in his "Life and Times of Benjamin Franklin," recently published, thus refers to the labours of this eminent man in the development of electrical science. "He devoted the leisure of seven years and all the energy of his genius to the science of electricity, which gave a stronger impulse to scientific inquiry than any other of that century. He taught Göethe to experiment in electricity, and set all students to making electrical machines. He robbed thunder of its terrors and lightning of its powers to destroy."

CORRESPONDENCE.

PATENT OFFICE LIBRARY AND MUSEUM OF INVENTIONS.

To the Editor of the Telegraphic Journal.

Sir,—It may not prove uninteresting to many of your readers to know what is being done relative to the proposed erection of a new Patent-office Library and Museum of Inventions.

The thorough inadequacy and inconvenience of the Chancery-lane Patent-office, and the hopelessness of ever rendering the same efficient for the use of the inventors and the public, are now well known, the inconvenience being so great that not only is the ordinary business impeded, but the advantage which should accrue to inventors, manufacturers, and others, from being able to inspect, free of charge, the valuable collection of scientific books and specifications contained in the library, are almost nugatory. The library is nearly choked up with confusion and constantly increasing mass of books and specifications of the highest practical and scientific value, and had not the approaches in the library been brought into temporary requisition some time ago for library purposes, access to the library itself would now be impossible. Public attention having been directed to this, the council of the Inventors' Institute, in December last, devised a series of plans, providing, amongst other things, for the erection of an accessible and well-arranged Patent-office Library and Museum of Inventions immediately in the rear of the present National Gallery in Trafalgar-square. The leading feature, however, of their plans was to promote the erection of a building, or blocks of buildings, in a central position, in which might be located the various representative scientific, literary, and art institutions now scattered over all parts of London, thereby providing an appropriate habitation for science, literature, and art in all their varied branches; the erection of a national gallery of paintings and sculpture worthy of this great metropolis, together with an accessible and well-arranged Patent-office library and museum of inventions, comprising a complete record of that inventive and industrial progress which has so long maintained the pre-eminence of this country amongst the nations of the earth. Land sufficient for the purpose, immediately in the rear of the present National Gallery, was surveyed, and the total cost of purchasing a site of about five acres was estimated at about £700,000. A building suitable for the purpose, covering that space and the site now occupied by the National Gallery, with a frontage to Trafalgar-square, forming a fit adornment of one of the noblest sites in Europe, could be erected at an estimated cost of about £500,000. The Inventors' Institute plans also involve and provide for the construction of a magnificent new street, extending from Agar-street, Strand, to the top of the Haymarket, by Coventry-street. This street would be practically on a level, and well calculated to relieve the accumulation of cross traffic which will occur and be severely felt when the railways now in progress in the neighbourhood of Charing-cross are completed. A large portion of the new street would form the back of the proposed new building, and a plot of ground on the other side would be available for the erection of a new barracks.

A deputation of the council of the Inventors' Institute, introduced by Lord Richard Grosvenor, M.P., submitted these plans, about two months since, to her Majesty's First Commissioner of Works, and suggested that the accumulated surplus income of the Patent-office, now amounting to nearly £300,000, should be devoted towards the erection of a Patent-office Library and Museum of Inventions on the proposed site; but the Government being then apparently in favour of removing the National Gallery to Burlington House, and the Patent Museum to South Kensington, no definite satisfactory result could then be obtained. Subsequently a committee was moved for in the House of Commons, and appointed "to inquire into, and report upon, the necessity for the erection of a new Patent-office Library and Museum of Inventions," and the Inventors' Institute deputed two of their council, viz., Sir David Brewster, K.H., LL.D., F.R.S., and Robert Richardson, Esq., C.E., to give evidence in favour of their proposals. Sir David Brewster, in his evidence before the committee, gave it as his opinion that the whole expense of the site, and of erecting the proposed buildings, might, if necessary, be defrayed within a limited number of years, by holding in the buildings, and in the court-yard and open space around them (which might be temporarily glazed over for the purpose) periodical exhibitions of the art and industrial products of the country, small sums being charged for admission, as in the case of the Great Exhibitions of 1851 and 1862. He also stated that the stimulating effects of such exhibitions, if held in so central a position as Trafalgar-square, and conducted by Governmental authorities, aided—as then they might be—by the concentrated scientific, literary, and art intellect of the nation, would develope the manufacturing interest of the country to an almost incalculable extent.

Mr. Richardson stated, in his evidence, that although he recommended the adoption in their entirety of the Institute's comprehensive proposals, yet he thought that inventors would be satisfied if only such a portion of the complete plans as would provide a suitable Patent-office, Library and Museum of Inventions in the rear of the National Gallery were in the first place carried out. A site in the rear of the National Gallery, sufficient for such a Patent-office Library and Museum, would be less expensive, he stated, than any of the other sites which had been suggested. It would be more readily accessible to inventors and the public, and by bringing the proposed Museum of Inventors into immediate proximity with the galleries of our art institutions, would present advantages which no other site could afford

L. Marsden Latham,
Secretary to the Inventors' Institute.

PARLIAMENTARY NEWS.

INTERNATIONAL TELEGRAPHIC COMMUNICATION.

Sir C. Douglas asked the Under-Secretary of State for Foreign Affairs, if the French government had addressed a circular to the various powers, inviting them to participate in an international congress, for the purpose of regulating telegraphic communications in Europe; and if so, whether her Majesty's government would comply with that proposal.

Mr. Layard said that he had seen it stated in the newspapers that such a circular had been issued; but no copy of it had been sent to the British Government; and for this obvious reason, that telegraphic communication in this country was in the hands of private companies, while in the other states it was entirely under the control of the respective governments. He was not aware whether any communication had been made to our telegraph companies.

TELEGRAPHIC NEWS.

Electric Bells.—Messrs. Moseley & Son, of King-street, Covent-garden, have been appointed sole agents in England for Grenet's electric bells.

The Main Sewerage of London.—Between the chief pumping stations attached to the above great undertaking, electro-telegraphic communication will be provided, so that in case of an accident taking place at any particular station, an instantaneous notice thereof can be given to all the others.

Electric and International Dramatic Club.—In our brief critique on the late performance at the Cabinet Theatre, we omitted to award the credit due to Mr. James Cook for his able representation of *Carlitz* in "Love in Humble Life." The arduous character was sustained throughout with consummate ability. Mr. Cook's personification evinced dramatic talent of no mean order, and was warmly applauded.

Electric and International Telegraph Company.—The directors have resolved to recommend to the proprietors, at the general meeting to be held on Wednesday, the 3rd of August next, to confirm a dividend of £4 per cent. for the last half-year. We regret our inability to publish the report and accounts of this company, as we have done on previous occasions, because on application at the chief office for a copy of the same, a few hours before we went to press (and within four days of the date for which the meeting is announced), we found that the report and accounts were not printed.

Conversazione at St. Bartholomew's Hospital.—On the 22nd inst., by invitation of the treasurer, a brilliant *conversazione* was held in the hall of St. Bartholomew's Hospital. The hour named was nine o'clock, and soon after that time the large hall was thronged with a distinguished company, while long after ten the carriages continued to roll up to the doors. In the great square the electric light shed its dazzling rays upon the noble fountain, which plashed amid the trees that adorn the quadrangle, and brought into relief every detail of the architecture of this famous medical school and "town house" of charity. In a room on the ground-floor light refreshments were served, and the staircase was ornamented with a profusion of rare and beautiful flowers and shrubs. The great hall was a blaze of light, and on its walls were crowded paintings of great merit, both old and new. On stands about the room were exhibited a host of interesting and beautiful things—scientific instruments, among which Ross's microscopes were not the least attractive; paintings, miniatures, photographs, electric and magnetic telegraphs, whose tinkling bells were pleasant to the ear—in a word, everything that was likely to add to the enjoyment of men of science, or of the ladies who accompanied them. The *conversazione* was very charming, and it is no wonder that the visitors lingered as they did, chatting here, examining something of scientific novelty or importance there, and at the last the electric light lit them out of the great gateway thoroughly satisfied with the pleasure they had experienced.

Watson and Horwood's Electric Fire and Burglary Alarms.—These alarms, although of course unable to prevent the origin of fire, are nevertheless so complete in their construction, that, immediately upon the air of any room becoming heated above its natural temperature, it is announced by the ceaseless ringing of a bell, thereby allowing time for the preservation of life, with freedom from the agonizing sufferings too often attendant upon this most dreaded and desolating of all calamities; and also the removal of valuable property (without damage), which if once destroyed could never be replaced. The same continuous ringing also occurs upon the opening of any protected door or window more than the space of an inch, so preventing the ingress or egress of any person without an instantaneous alarm being given. The apparatus by means of which these important effects are produced is so simple in its construction, that it is manageable even by a child, and its operations may be suspended during the day, or when desired, by the turning of a small handle similar to that of an ordinary bell. The whole is neatly enclosed in an ornamental wooden case, to match the furniture of the room, within the small space of about twelve inches; and the communications throughout the house can be laid on without the slightest blemish to the decorations or inconvenience to the occupants. These alarms may be seen in operation at the office of the patentees, 51, King William-street, London.

THE BEHRING'S STRAITS TELEGRAPH.—Mr. Perry M. Collins is the projector of this great enterprise. The Russian Government is constructing a line across the continent of Asia to the mouth of the Amoor river, and from this point to the mouth of the Columbia is about 6,500 miles. It is this gap which the company of Mr. Collins proposes to fill. What they ask of Congress is the right of way across the public lands, the grant of a square mile of land at each station, the stations being 15 miles apart, and the payment of $50,000 a year for the Government use of the telegraph.—*Scientific American.*

THE MANUFACTURE OF THE ATLANTIC CABLE.—We are given to understand that this important work is progressing to the satisfaction of the Atlantic Telegraph Company. Last week several wire-covering machines were sent from the manufactory of Mr. A. Smith, Princes-street, Leicester-square, to the works of the Telegraph Construction and Maintenance Company, East Greenwich. The Great Eastern now lies in the Medway, and is being fitted with iron water-tanks, in which the cable will be coiled as it is perfected. The big ship is again an object of curiosity, and the available spaces in London are posted with large placards announcing cheap trips to the Medway and a view of the Great Eastern.

NOVEL RAILWAY BREAK.—A letter from Italy says that an ecclesiastic of Cagliari, one M. Garau, has most ingeniously applied the principle of electricity to the construction of a break for railway carriages. A single touch of the electric wire produces an instantaneous stoppage of the wheels, and, by a peculiar arrangement of the mechanism, M. Garau has succeeded in obviating the dangers arising from a sudden check in the movement of a train of carriages. The model certainly works most satisfactorily, and the invention has already attracted much attention in France as well as in Italy.

A NEW SUBMARINE VESSEL OF WAR.—Towards the close of last year the *Times*, in an article descriptive of Russian preparations for war, stated that one means of defence for the Neva, approved by the authorities, was a submarine boat, of colossal dimensions, in the construction of which 200 tons of iron and steel were to be employed. "Great secresy" the leading journal observed, "is being used about this boat." We can, however, state that it is to have engines worked by compressed air, to have a very strong beak, with provision for attaching large cylinders charged with gunpowder to the bottoms of vessels, to be fired by electricity. The parties navigating the vessel will see what they are doing by means of "bull's eyes," and they will be able to regulate the depth at which they swim, which will never be at any great depth from the surface.

MISCELLANEA.

RAILWAY CALLS.—The amount of railway calls falling due this month exceeds £1,500,000. This sum will raise the total subscribed from the 1st January to the end of this month to about £8,250,000.—*Economist.*

NEW SILVER COINAGE.—A contemporary states that it is in contemplation to recall the whole of the silver coins now in circulation, and to replace them by an entirely new coinage of that metal. The change is to take place ere many months shall have passed away.

BOILED TELEGRAPH WIRE.—Boiled wire is used by some telegraph companies, and the process of preparing it is thus described:—"The wire, in coils, is placed in a large iron cauldron, filled with linseed oil, and boiled about fifteen minutes, when it is presumed to be 'done.' By this process it receives a coat of glazing, which preserves it from rust. The wooden blocks, or braces, by which the insulators are placed, are also boiled, but in different material. They are made of sycamore wood, and are boiled—100 at a time—for a period of one hour, in ordinary coal tar. The effect of subjecting the sycamore to this process is to render it secure against warping or cracking from sun or rain."

SILVER ALLOYS.—Some new alloys of silver have been reported to the Academy of Sciences at Paris, by M. Peligot, the chemist to the French Mint, in consequence of the proposition of the Imperial Government to reduce the standard of the silver coinage. The new coinage was to consist of 835 parts silver, and 165 parts copper, but M. Peligot has made experiments to ascertain how the introduction of zinc, or the complete substitution of zinc or copper, would affect the alloy. He has found that alloys of the legal standard, in which part or the whole of the copper was replaced by zinc are remarkably malleable, and when rolled are perfectly homogeneous. They are of a beautiful white colour, but the binary alloy of silver and zinc are somewhat yellowish. The fusibility of the zinc alloys is greater than the copper; they are very sonorous and elastic, and if made brittle by hammering, the malleability is restored by heating. The study of the atomic alloys showed curious results. Equal equivalents of silver and zinc, or two equivalents of silver to one of zinc gave malleable alloys, while the compounds of one equivalent of silver and two equivalents of zinc, and also of two equivalents of silver and three equivalents of zinc are too brittle to be rolled. As a matter of economy, M. Peligot recommends that his government should employ zinc to reduce the value of the present money, the price of zinc being only one-fifth that of copper. Another recommendation to the zinc alloys, is the fact of its blackening less readily with sulphuretted hydrogen than the copper compound, copper indeed seeming to increase the discoloration. An alloy of 800 of silver and 200 zinc will keep its whiteness in a solution of polysulphide, which will rapidly blacken the legal alloy of copper and silver.

THE PASSIVITY OF METALS.—The change which metals seem to undergo through the action of certain agents has been studied by M. W. Heldt, who asserts that the phenomena are produced on the surface of certain metals whose nitrates are insoluble in nitric acid. It is to the insoluble layer produced that the "passivity" is due, and not to a peculiar electro-dynamic state, or to "polarisation." Those metals alone whose nitrates are soluble in dilute nitric acid, and insoluble in the concentrated acid, present these phenomena. In copper and tin the insoluble layer may be seen by the naked eye; in other materials it requires a glass. Acidulated water removes it easily, and the metal returns to its original condition.

LATENT HEAT.—The philosopher who first investigated the phenomena of latent heat, and who by the inquiry contributed so much to experimental philosophy, was Dr. Black, about the year 1757. Before this period it was supposed that the state of fluidity was occasioned by the addition of a very small quantity of heat to a solid, when once raised to its melting point, and this was, *primâ facie*, a reasonable supposition; it was also, and with equal appearance of probability, imagined that during the conversion no greater addition of heat was received than the thermometer indicated. It very frequently happens that facts which we have every day an opportunity of observing are disregarded, however curious they may be; whilst those that occur rarely are much more likely to arrest our attention. In consequence of this craving for novelty many highly interesting particulars escape us, till some master-mind, some philosophic spirit interposes, and opens from old materials a new and extensive field of inquiry. Thousands must have observed, before the time of Black, that however cold ice may be it soon becomes heated to its melting point when brought into a warm room, but that nevertheless it is a long time before it is entirely re-converted into water, and that a heavy snow always remains on the ground for a very long time after the breaking up of a frost, its re-conversion into water being exceedingly gradual. Now, if the state of fluidity be occasioned by a small addition of heat to a solid raised to its melting point, the ice and snow ought to vanish presently, the heat continuing to be accumulated from the air around. This occurred to Dr. Black, who immediately set about inquiring what becomes of the heat that must keep continually entering the ice, without producing its liquefaction. If a piece of ice be suspended in a warm room the effect of the warm air is rendered evident by the stream of cold air that constantly descends from it, and which may be felt on the hand. If the drops of water, as they fall from it, be received on the bulb of a thermometer, the instrument will indicate the same temperature as the ice itself, viz., 32°. Dr. Black made the following experiment:—He filled two similar globular glass vessels with water; one was afterwards frozen, and the other cooled as nearly as possible to the same point; they were then carried into a room the temperature of which was 47°, there being no other difference between them than that one contained water and the other ice. In half an hour the vessel containing the water had acquired the temperature of 40°, but in the other it required ten hours and a-half to melt the ice and to raise the water to 40°. Now the access of heat being in both cases the same, and at the rate of 7° per half hour, it follows that in twenty-one half hours (the time required to thaw the ice and elevate the temperature of the water to 40°) it would have received $7 \times 21 = 147°$. The difference, therefore, between the increase of temperature in the ice and water vessels, with equal accessions of heat, is *one hundred and forty degrees*, which will express the quantity of sensible heat rendered *latent* by the operation of liquefaction. The same number is brought out by other methods of experimenting. Equal weights of water at 32° and 212° will, as we have shown before, produce on mixture the mean temperature of 122°; but equal weights of *ice* at 32°, and water at 212°, only produce, after the ice has melted, a temperature of 32°; the water loses 160°, while the ice acquires only 20°. Now, 160°—20°, gives 140° as before, for the quantity of heat expended in changing the ice to water; for the quantity of latent heat on which the fluid state depends. But this heat is not annihilated, although to the feeling and to the thermometer it is insensible. This is proved by the following experiment, also made by Dr. Black:—When the thermometer stood at 22° in the open air he exposed two similar vessels, one full of water and the other of brine, both at 52°; both lost heat till they were cooled to 32°, after which the brine (which does not freeze till cooled down to 4°) continued to lose heat without interruption, and gradually reached 22°, the temperature of the air; but the pure water remained stationary at 32°, when ice began very slowly to form. Now, can anything be plainer from this experiment than that the reason of the water refusing all of a sudden to give out heat is, that its temperature was maintained by the heat which it absorbed during its liquefaction, and which it slowly evolved during its conversion into ice? Dr. Thomson has concluded, from many experiments, that the quantity of ice which forms suddenly on the agitation of water, cooled down below the freezing point, bears always a constant ratio to the coldness of the liquid before agitation, and that from analogy it was probable that for every five degrees of diminution of temperature below the freezing point, without congelation, one twenty-eighth of the liquid freezes suddenly on agitation. Therefore, if water could be cooled down twenty-eight times five degrees below 32°, without congelation, the whole would congeal instantaneously on agitation, and the temperature of the ice would be 32°. Now, observes Dr. Thomson, it deserves attention, that $5 \times 28 = 140$, gives us precisely the quantity of heat which, according to Black's experiments, enters into the ice, in order to convert it into water. Hence it follows that in all cases when water is cooled down below 32° it loses a portion of the heat which is necessary to constitute liquidity.—*Noad's Lectures on Chemistry.*

Very Fair.—A Cape of Good Hope paper states that Port Elizabeth has a population of 21,000. It has four banks, three episcopal churches, fifteen dissenting churches, a theatre, an opera, a public library, a college, two literary institutions, and an electric telegraph *in esse* and railways *in posse*. There are seldom less than thirty ships in the bay.

Conscience Money.—The moneys remitted to the Chancellor of the Exchequer by sundry persons for conscience' sake in the past financial year, ending the 31st of March, amounted to £7,400. In the previous year conscience rendered up £10,422. From this statement it would appear that we are either more conscientious or less honest this year than last.

Wire Tremors.—Comparisons and registration of wire disturbances, or earth currents, have induced me to believe that they are all electro-magnetic, occasioned by action of atmospheric currents, and, consequently, only indirectly caused by solar action. I believe that whenever the magnetic instruments of observatories have been affected (as in a magnetic storm), and whenever telegraph wires have vibrated to nature's operations, or have been disturbed by earth currents (so called), there has been a concussion, a commotion, or a much developed antagonism of air currents, somewhere within the farthest atmospheric limits, if not within a hemisphere. A spider in its web "feels at each thread, and lives along the line." Does not the earth—even more than the telegraph wire—conduct electric or magnetic influence? Is not an earthquake felt, even by the vibration alone, thousands of miles? And can a violent explosion—lightning and thunder—anywhere fail to cause vibratory or electric effects in some if not in many directions? —*Admiral FitzRoy*.

Amber.—This is a subject on which a great deal has been written. It has generally been classed among minerals, although avowedly originating from the vegetable kingdom. Nothing as yet as afforded a clue to the plant that may have produced it; nor has any plausible conjecture been formed from the flowers and insects sometimes imbedded in its mass. Its peculiarly resinous nature seems to point to some *Hymenœa* or to the *Binu Daunnara* as the parent plant; but there is no perfect identity between the produce of these genera and amber. Nor is it certain that all kinds of amber proceed from the same source; for its aspect often varies considerably, according to the beds in which it is found, which circumstance has led many naturalists to the belief that there are several amber-producing plants. In a paper addressed to the Academy of Sciences by M. Bandrimont, the composition of this anomalous subject is examined. Recluz has has already shown that white and opaque amber contains more succinic acid than the perfectly transparent yellow sort; Drapiez had analysed it and found it to contain carbon, hydrogen, and a small proportion of ashes, consisting of lime, alumina, and silica. M. Bandrimont, however, shows that it contains another element not hitherto mentioned, viz., sulphur. If a few fragments of amber be subjected in a test tube to a heat of distillation, and paper impregnated with acetate of lead be immersed into the white fumes evolved, it immediately turns black, thus unmistakeably denoting the presence of a sulphuretted compound. The proportion of sulphur contained in amber is not, however, very considerable, since our author fixes it at somewhat less than one half per cent. But under what form does it exist therein? Is it contained in the essential oil, or in the two soluble resins, or in the insoluble bitumen contained in the amber? M. Bandrimont does not tell us, but states that most certainly it is combined with organic matter, because it is evolved under the form of hydrosulphuric acid. —*Galignani*.

PATENTS.

APPLICATIONS FOR LETTERS PATENT.

1804. H. E. F. De Briou, protecting and preserving metals, such as iron, copper, and zinc used in the construction of ships, or in the protection of their sides and bottoms from oxydation and corrosion from the action of the sea water; and for protecting all submerged substances, such as chains, anchors, cables, and every oxydable metal submerged in water or exposed to atmospheric influences.

1820. W. Booth, rendering security to railway travelling by effecting ready and easy communication between the guards, passengers, and engine-drivers on railway carriages, or other public conveyances where the same may be applicable.

1823. A. V. Newton, improvements in electro-telegraphic apparatus.

1840. P. Æ. Le Boulengé, an electro-balistic chonographe.

NOTICES TO PROCEED.

661. E. F. Ruffin, improvements in marine and land signals.

680. W. A. von Kanig, improvements in railway telegraphs and signals, and also in the permanent way and carriages for preventing railway accidents.

758. T. W. Rammell, improvements in pneumatic railways and tubes, and apparatus connected therewith.

PATENTS SEALED.

241. N. J. Holmes, improvements as applied to the regulation of machinery for covering telegraph cables, wires, and other similar articles.

244. G. Canouil, an improved alarum and signalling apparatus.

260. E. T. Hughes, improvements in submarine batteries.

PATENTS WHICH HAVE BECOME VOID.

1772. T. Cobley, improvements in the manufacture of metallic and earthy silicates, or siliceous compounds of the same, from the metallic and earthy bases or their salts and soluble alkaline silicates, the formation of alkaline acetates or caustic alkalies, and application of the same.

PATENTS ON WHICH THE STAMP DUTY OF FIFTY POUNDS HAS BEEN PAID, AND DATES OF THEIR PRODUCTION FOR CERTIFICATE.

1907. J. Rylands, T. G. Rylands, and P. Rylands, improvements in joining wire for telegraphic conductors and other purposes.—31st July, 1861.

PATENTS ON WHICH THE STAMP DUTY OF ONE HUNDRED POUNDS HAS BEEN PAID, AND DATES OF THEIR PRODUCTION FOR CERTIFICATE.

1998. F. H. Holmes, improvements in magneto-electric and electro-magnetic machines.—20th July, 1857.

PRICES CURRENT OF INSULATING MATERIAL.

TO CORRESPONDENTS.

J. H. W.—We will supply the necessary particulars through the post.

W. T. Henley.—Too late for insertion this week. We go to press on Friday forenoon.

R. F. Murphy.—The cable you refer to was subjected to a variety of tests in our presence, but all efforts to get a "kink" in it proved unavailing.

T. R. S.—Make your case known to the manager, and if he does not remove the nuisance, write us again.

Eugene F.—The conduct of the said manufacturer is unworthy of consideration. He has lost his temper, and we shall leave him in peace to find it.

As information respecting Improvements, Extension of Lines, and Progress of New Undertakings will at all times be most acceptable, we hope that our readers will kindly render us assistance, by furnishing us with brief notices of events and occurrences in connection with electrical and scientific progress.

Communications intended for publication must be authenticated by the names and addresses of the writers; not necessarily for insertion.

Letters relating to Advertisements are to be addressed to the Publishers. All other letters and communications to be addressed to the Editor of the *Telegraphic Journal*, 4 & 5, Suffolk-lane, Cannon-street, London, E.C.

The *Telegraphic Journal* can be had of Messrs. Smith & Co., Strand; J. Onwhyn, Catherine-street, Strand; Messrs. Dawson & Co., Cannon-street, E.C.; Messrs. Kent & Co., Paternoster-row, London. Messrs. Heywood & Co., Manchester; at the various railway stations; and of all news-agents, &c., &c.; or it can be supplied, if preferred, direct from the Office on the following terms:—

Quarterly, 4*s*. 4*d*. | Half-yearly, 8*s*. 8*d*. | Yearly, 17*s*. 4*d*.

TO ADVERTISERS.

The *Telegraphic Journal* is the most effective medium for inventors, patentees, contractors, manufacturers of insulating materials and electrical apparatus to submit their various specialities to the consideration of secretaries and managers of telegraph or railway companies, and other persons engaged in electrical and telegraphic pursuits.

Clerks, assistants, manipulators, and instrument makers, seeking employment, &c., will find the *Telegraphic Journal* a ready means of making known their requirements.

Advertisements must be delivered to ensure insertion before Seven o'Clock on Thursday evening in each week. The charges for Advertisements are—

	£. s. d.		£. s. d.
Whole page	4 4 0	Quarter page	1 7 6
Half ditto	2 10 0	Four lines and under (single col.)	0 3 0

Single Advertisements from the country must be accompanied with stamps in payment.

FORCE AND FORM.

CONTRIBUTED BY B. M.

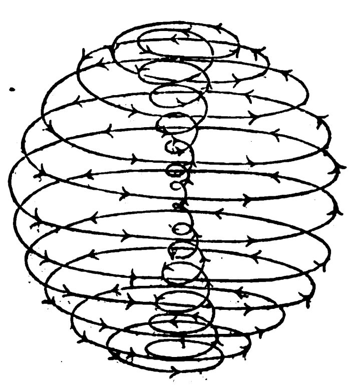
IV.

WITHOUT going at present into the proofs of the forms of active force, or, if you like it better, the forms of motion, I will try to set forth by delineation and description what I mean by an atom; as being force in a form; that is, as I understand it, as set forth by its author, though he in his day had no idea of the confirmations, that we now have in electro-magnetism, and in our better acquaintance with electricity and magnetism. This accumulation of knowledge, no doubt, has led our leading scientific men towards the rejection of the Newtonian hard dead atom, as the present theory of light has caused his vacuum to be rejected. One wonders how such a notion could ever have been held. How could one body act upon another at a distance without the intervention of a nexus? There could be no such thing as attraction and repulsion. It would be simply, as the Rev. W. Jones of Nayland has put it, "a *pulling* without any hold, and a *pushing* without touching." But the hard dead atom requires the vacuum, and the vacuum the hard atom; they are essential to each other. If there is no vacuum, then there can be no hard, unyielding atom, else our universe would be one hard, dead, solid mass, where there could be no motion, no life—a universe of solid brass. But as it is agreed that there is a plenum, and we still have life and motion, let us try to understand how that is, and not only that, but how *force induces force*, for this is the whole question at present exciting so much interest and so much discussion, and is set forth under so many forms, such as "co-relation of physical forces," "mechanical equivalent of heat," "the laws of energy," "electro-magnetism," "magneto-electricity," "static electricity," which is divided into so-called "resinous and vitreous," "law of charge, discharge, and retardation," as applied to electricity, and a wilderness of other laws and forms and special instances; all good as material, but as laws and formula, rubbish! No wonder our telegraph men speak of electricity as if it were beer or broth, and of magnetism as if steel could be soaked in it and become saturated. Of experience and experiments we have at present an *embarras des richesse*. We want now a little digestion of these crude material, and then a little assimilation. A true law of force in effort and in act will be our solvent. Then induction, conversion, and co-relation will become understandable. To understand this matter we must begin at the beginning, we must begin with the atom, which according to our theory is *force in a form*. I know of some who say, "We cannot understand your atom; it begins in nothing and ends in nothing. Give us Newton's sensible, solid piece of matter, which the mind can grasp; not so *your* atom, which is an aggregation of points, and a point has neither length, breadth, nor thickness; consequently is nothing." I can only say to this that it is not the theory of an atom as propounded by Swedenborg, or Boscovich, or as understood by Faraday, and I can only wonder that, after having read any one of these authors, it can be so understood. What they say is, that an atom is a centre of force, and of course a centre is a point; but the centre of every solid is a point; but the solid is not therefore made up of points. Now, as far as understandability goes, what difference between the hard incompressible atom and our soft and yielding one? Nay, since a vacuum is untenable, the yielding elastic atom can be easily understood, but the other cannot possibly. And even if it could, and simply because it has length, breadth, and thickness to begin with, why so has ours. "Oh, but you begin in a point;" and so does the form of your hard, impenetrable atom begin in a point too; and if you take away the form of your hard atom, what have you left of it, but hardness, and deadness, or, what is the same thing, inertia; but deadness is nonentity or nothingness, and what is hardness if it is not resistance or force? So that you see if your atom is not force in a form it is nothing.—Q. E. D.

If there is such a thing as force extant in nature, then it must begin to evolve itself a form in a point, for all form must begin there; so says geometry, and if that is not satisfactory, then I suppose our confidence in the multiplication table also is entirely misplaced.

Now, as I have every belief in the multiplication table and in the axioms of geometry, I shall take them for granted as heretofore; therefore our force begins to evolve itself a form in a point. If force begins to exert itself in a point, then it must be by certain effort or tension, and it is clear that this tension must be in every direction, because this point is the initiament of a solid; therefore its fluxion must be in three directions corresponding to the three dimensions of a solid, namely, length, breadth, and thickness. Not only that, but it must be in such a form that it can be a living and active force under all circumstances: it may be passive relatively, but active absolutely; for quiescence is death to the higher order of beings, and to simple matter it is annihilation. Now, to fulfil these conditions there is only one form that I can conceive, or that seems to be possible, namely, the perpetual spiral, or vortical, as it has been called. The annexed figure shows the fluxion of the vortical.

N



S

In this figure is indicated the external spiral of the sphere and its polar cones. The atom as here represented is the microcosm, of which the earth is the macrocosm, and will go far to explain the apparent anomalies of the magnetic polarities of the earth, if the base of the north polar cone be taken to represent the parallel of latitude in which the earth's north magnetic pole is apparently situated, or north magnetic poles, as some have imagined to have observed, yet from the very nature of attraction one would have supposed that no one could have entertained such a notion; for two polarities of the same name could not exist

together without coalescing, and two of opposite names could not without neutralizing each other; but the poles cannot be of the opposite names, for the earth's magnetism is not neutralized; and if it were possible that there should be two of the same name, they would coalesce, therefore no indication of duality from that cause could be given, consequently the apparent indications of duality must be referred to some other cause. Magnetism abundantly proves what is here stated.

These, and other apparent eccentricities of the magnetic meridians, have been accounted for in another manner by the first propounder of this theory of atomic motion. He affirms that the magnetic poles of the earth coincide with the poles of the ecliptic; therefore, the poles of the earth revolve round the magnetic pole, that the north pole makes one revolution in 386 years, and the south in 1,080 years; and he says that these will form a cycle of 5,400 years, and this he considers to be the principal cause of the magnetic variation. On these data he has calculated the variations for several places down to the 20th century; but many of his results differ widely from the variations as since found by observation. Even if this were the reason of the magnetic variations, his results could not very well be correct because of errors, and of disturbing causes of which he has taken no note. For example, he states that the periods 386 years and 1,080 years make a cycle of 5,400 years; but they do not, for though in that time the south pole would have made five revolutions, it would take four years more for the north pole to make fourteen revolutions, consequently at the end of 5,400 years they would not be in the same relative position as at the beginning. Instead of a cycle of 5,400 years they would form one of 104,220 years. He also takes the ecliptic to be at an inclination 22° 30′ to the equinoctial, but it is at an inclination of 23° 28′; besides he takes no note of *precession* and *nutation*.

Precession is a motion of the earth's poles round the poles of the ecliptic at an angle of 23° 28′, but evidently distinct from the one stated above, its period being upwards of 25,000 years; and nutation is an undulating movement given to that course, taking nineteen years to complete a concave and a convex undulation. These errors and omissions, of course, would vitiate the result, if even the principles on which the calculations are based were correct in the main. But the greatest difficulty to me is to understand how one magnetic pole can revolve more than twice as rapidly as the other. I have no mechanical formula to reduce that to, therefore to me it is just unintelligible. However, for the present we will leave these speculations, and return to our figure of motion. Beginning, then, at the *point*, the centre of the sphere of force, it begins to actuate itself in motion, thence flowing in a spiral cone to the extremity of its sphere of potency, then recurving and flowing in a spherical spiral over the circumference of its sphere of potency to the opposite pole, where it re-enters by a similar cone from circumference to centre, thence to renew its course to the circumference as before in endless gyrations; and this is the most perfect form of motion, the perpetual vortical. Of course this form of motion is not really progressive in its formation, as is made apparent by this description, no more than a solid is by the progressive description from point, line, surface, to full form, but being the simplest of all entities *is* not bing composed of parts that can exist apart from the whole, and this description is simply that of its fluxion.

Now, it will be seen clearly from this figure of motion that the like poles of two such atoms must repel each other, whether they be the poles of issuing or entering force, for in both cases there are two opposing forces either central or circumferential. It will also be seen that at each pole the force moves in two directions. At the issuing or north pole, taking the earth's polarity as a standard, it not only flows out from the centre, but recurves and flows back over the circumference; and at the south pole this circumferential force again recurves and flows back to the centre. It will be as clearly seen by an inspection of the figure that the unlike poles must attract each other, for not only will the central spirals coincide, but will mutually flow into each other; the circumferential spirals will also do the same, and this will produce a mutual approach of their centres and a coalescence of their spheres. All this will be easily understood by an inspection of the direction of the arrow-heads in the figure. These are the first essentials to be understood of a unit of force in a form, namely, the mode of its actuation into a solid, and of its mode of coligation with other atomic solids.

EXTENSION OF THE TELEGRAPH.

Our own correspondent at Natal, in the letter published in our last, appeals to the liberality of the inhabitants of this colony in the matter of the extension of the electric telegraph to D'Urban. We are not disposed to underrate the advantages which we should enjoy by the construction of a line of telegraph to the sister colony, nor will we say the Parliament should be grudging in granting the required help; but previous to any farther monopoly being granted to the existing company, or any other company which may be formed, a clear and definite understanding ought to be come to as to the precise benefits which the contracting parties are to secure to each other. Unfortunately for the Cape, when the Parliament had under its consideration the terms upon which the line between Cape Town and Graham's Town should be constructed, a deaf ear was turned to the arguments of those who maintained that the work was one which ~~should be undertaken~~ without the help of a company, the Government itself constructing and working the line. One or two of the members of the Assembly, it will not be forgotten, allowed themselves to be button-holed and talked over by the gentleman who, report says, subsequently made such a good thing of the transaction; and the upshot of the whole is, that the colony has to pay an annual subsidy of £1,500 for the transmission of Government messages, and when private individuals have to use the line, they are subject to a rate of charges which we believe to be without a parallel in any other portion of the globe. We are far from saying that the Government could have constructed the existing line for the same sum as it has cost the company; indeed, it is highly probable, if it is not absolutely certain, that the figures would have borne no proportion to each other; but what we do say is, that whenever an extension of the line is spoken of, it must be regarded as a *sine qua non* that the existing scale of charges is not to apply to any additional length of line. We fear that it is too late now to argue that the fees for the transmission of messages between Cape Town and the other stations ought to be modified except, perhaps, in one respect; the colony has made its bargain, and to it we must adhere. But if the Parliament is solicited to grant an extension of what is to all intents and purposes a monopoly, the interests of the tax-payers must be more closely looked after. Even now we have reason to hope that if a pressure were brought to bear upon the Government, it might turn out that the rule by which the name and address of the person dispatching, and that of the person receiving the message, are treated as forming part of the message itself, was an after-thought, and we should be glad to find that one of the members of Parliament had moved for the production of the correspondence between the Government and the manager of the company upon this point.

In connection with this subject, we may again direct public attention to the discussion which recently took place in the House of Assembly upon this item in the estimates, in the course of which the Colonial Secretary accounted for the excess in the present charges, over those estimated by Mr. Wollaston two or three years ago, by saying that the line had cost in the construction three times the amount first put down. In reply to this, one of the members of the Assembly asserted that the line had been completed within the estimated sum, and the statement was allowed to go forth uncontradicted. Now, at first sight, it would appear as if both these statements could not be correct, but that if Mr. Rawson was right, Mr. Wood—for we think it was he who replied—must be wrong. A moment's consideration, however, may tend to clear up the discrepancy, and we think we are not far wrong when we conclude that Mr. Rawson's figures included the very handsome douceur which is said to have been paid to Mr. Pickering by the company, while Mr. Wood's only embraced the actual money spent on the work of construction and in the purchase of instruments

and other materials. Again, the Colonial Secretary stated, in the course of the debate, that during the time which had then expired, subsequent to the opening of the line, the government had transmitted or received messages, which, if paid for at the scale charged to the public, would have fully made up the amount of the annual contribution. There can be no doubt but that the greater part of these messages was rendered necessary by the fact of Parliament meeting for the first time in Graham's Town, and the sum of £1,500 is doubtless made up by including the two or three *Gazettes Extraordinary* which were transmitted in this way to checkmate the late litigants in the matter of "the obnoxious resolution," and to enforce the new tariff of customs dues. In future sessions, we may be allowed to hope that the same necessity will not exist for such lengthy messages between Cape Town and the other end of the line; for even should the next Parliament assemble in Graham's Town—a contingency which we neither expect nor fear—we trust that no *ex post facto* Acts will render the ordinary communication by post too slow for the purposes of Government.

There is also another point which must not be overlooked in the event of a further contract being entered into with a foreign company, whereby we are sanguine a good deal of the uncertainty in the transmission of telegrams would be avoided. The imposition of a fine for every day during which the communication was interrupted would only be a fair and equitable arrangement. The present company has been fortunate enough to secure a contract on far more favourable terms than would ever be given again, but the colony will have gained experience from the working of the existing line, and future negotiations must be conducted on a totally different basis.—*Cape Argus.*

REPORT OF THE DIRECTORS OF THE UNITED KINGDOM ELECTRIC TELEGRAPH COMPANY, LIMITED.

When the directors met the shareholders at the last annual general meeting they were anticipating the speedy opening of the Company's second trunk line to the north, and the completion of the local subscriptions to enable them to extend the Company's wires into South Wales and the West of England.

At that time the entire working system of the Company was comprised in the single line of electric telegraph between London, Birmingham, Manchester, and Liverpool, and the necessity to include the whole of the large telegraphing towns in the country was becoming daily more apparent.

It was felt both by the shareholders and the directors that to make the uniform shilling rate successful it must be widely applied, so as to ensure the reciprocal action of the large towns the one upon the other.

It was thought practicable to complete the main lines, embracing all the chief towns, last half-year, but various causes have prevented this, and it was not until May that the northern, and June that a portion of the South Wales and western section were opened for business.

From this cause the operations of the Company have not been on the extended scale that the directors anticipated they would be, although the Company has erected and opened within a limited period a system such as has previously required several years to construct.

The directors are happy to state that they have completed the subscription for the South Wales and the West of England lines, and that the necessary funds are subscribed to enable the Company to extend to Paisley, Greenock, Stirling, Perth, Dundee, Arbroath, Montrose, and Aberdeen.

The Company's lines will thus run from Aberdeen in Scotland, by Glasgow and Edinburgh, to London, and to Swansea in South Wales, and Plymouth in the West of England.

Since the directors last met the shareholders, the works completed and now in operation are as follows:—

The section from London to Leeds, and across to Hull and Manchester, and Wakefield to Manchester, connecting Barnsley, Beverley, Bradford, Chesterfield, Halifax, Huddersfield, Leicester, Loughborough, Mansfield, Northampton, Nottingham, Rochdale, Selby, Sheffield, and Todmorden, opened between the months of October and March last.

The section from Wolverhampton to Manchester, embracing Burslem, Congleton, Hanley, Macclesfield, Stafford, and Stone, opened between the months of October and March last.

The section from Leeds to Newcastle-on-Tyne, embracing East and West Hartlepool, Middlesboro', Stockton-on-Tees, Sunderland, and Thirsk, opened in February and May last, and in the present month.

The section from Newcastle-on-Tyne to Edinburgh and Glasgow, embracing Falkirk, opened in May last.

The section from Oxford to Bristol and Cardiff, embracing Gloucester and Newport, opened in June last.

The mileage of the Company in operation this time last year was 370 of line and 3,020 of wire; it now amounts to 1,305 of line and 7,591 of wire, and, on the completion of the Company's lines at present begun or undertaken, will reach 1,658 miles of line and 9,316 miles of wire.

It will thus be observed that many of the most important towns have been only very recently brought into operation. No conclusive evidence could therefore be obtained in the twelve months ending the 30th June of the practical working of a low uniform rate, and the directors, following as they conceive a wise policy, determined to adopt the same course as last year, and place all earnings and expenses to the credit and debit of the construction account, without attempting a division, which the amount of work to be got through, and the early period at which it was necessary to call the meeting, rendered almost impracticable.

The shilling rate has only now been extended over a sufficiently wide area to prove its capability of becoming remunerative; and the public have, so to say, had to be educated to its uses.

Since the more recent extensions of the Company have been completed, however, the increase in the traffic has been considerable, and at particular points, and on certain lengths, the directors have already made arrangements to increase the working powers of the Company's system.

Thus two additional wires are being run from London to Nottingham, three from Nottingham to Wakefield, and four from Wakefield to Leeds.

Four additional wires are being run from Birmingham to Wolverhampton.

A line of seven wires is nearly finished from Liverpool to Warrington.

The directors are also now arranging to run more wires from Newcastle-on-Tyne to Glasgow.

These additional works have somewhat interrupted the Company's business, but they were imperatively needed. The directors believe that the shareholders will approve the policy of giving every accommodation and encouragement to the full development of the system.

By these means the Company will have better duplicated and more effective lines, with a far greater number of wires than was originally contemplated, and will give to Liverpool, Manchester, Glasgow, and other places, additional direct communications, the want of which is at present found to be a drawback to the Company's operations.

The lines west of Bristol are progressing rapidly towards Plymouth, and from Cardiff towards Swansea.

The extension to Dundee and Aberdeen is commenced, and will be speedily completed, arrangements having been made with the Scottish Central and North-Eastern Railway Companies for the use of their lines. The erection of the wires to Greenock, North Shields, and one or two other important places contiguous to the Company's present system, is all that remains to be accomplished.

The capital of the Company on construction account amounts to £213,133 8s. 4d., the remaining lines and extra works will be completed for £25,000, and the Company's capital will thus be £238,133 8s. 4d. For this the Company will possess 1,658 miles of line, and 9,316 miles of wire, and the working plant.

The property of the shareholders, therefore, will have been created at less expense than that of any existing Company, although the lines, apparatus, &c., are of the most efficient and improved description, and the system comprises only trunk lines to all the large towns.

The Company possesses in the large telegraphing towns a numerous constituency, amounting to 1,143, mostly consisting of persons using the wires.

Under these circumstances, the country has now an unusually favourable opportunity to secure a low, uniform charge in its telegraphic, similar to that in its postal, arrangements; and on the public it now depends to establish the permanency of the system in the one as in the other department of communication.

Henry J. Leeke, Chairman.

AUDITORS. { THEODORE B. JONES, of the firm of Theodore Jones & Co., Accountants, Moorgate-street.
P. STACE, Accountant, 15, Queen-street, Cheapside.

21st July, 1864.

ANNUAL MEETING OF THE UNITED KINGDOM ELECTRIC TELEGRAPH COMPANY.

THE annual general meeting of the shareholders of this company, to receive the directors' report and statement of accounts, and for the transaction of the usual business of the undertaking, was held at the offices of the company, Gresham House, Bishopsgate-street, on Saturday last, the 30th July. There was a numerous attendance of shareholders, and the following directors were present:—Alexander Angus Croll, Esq., deputy-chairman; Lord Alfred Spencer Churchill, M.P.; Robert Bryce Hay, Esq.; and W. H. Schenley, Esq. In the absence of the chairman of the company, (Admiral Sir Henry Leeke, M.P.), the chair was occupied by ALEXANDER ANGUS CROLL, Esq., C.E., the deputy-chairman.

The CHAIRMAN.—The secretary will read the advertisement convening this meeting.

Mr. ANDREWS, the secretary and manager of the company, read the advertisement by which the meeting was convened.

The CHAIRMAN.—The secretary will now read the report of the directors. (Given above.)

The CHAIRMAN.—He was very sorry they had not the presence of their chairman on that occasion; Admiral Sir Henry Leeke, however, had become so wearied out with the labours he had undergone in his legislative capacity that he had retired into the country in order to have a little requisite rest. The report which had just been read by the secretary gave such precise and complete information regarding the operations of the company, since the directors last had the opportunity of meeting the shareholders, that he should not have to trouble them with many observations of his. He could not help, however, expressing the gratification he felt in congratulating the shareholders on the present position and future prospects of the company. It was quite true that it would have been much more pleasing and agreeable to the directors to have met the shareholders with a report recommending the declaration of a dividend. He hoped and trusted, however, that no other meeting of the kind would be held at which the declaration of a dividend should not be associated with it, and he believed the time was not far distant when they should be able not only to declare a a high and satisfactory dividend, but also to pay back dividends from the first time that calls on capital account were made. (Hear.) These expectations were founded on what the company was doing at the present moment, on anticipations of a fair and reasonable increase of business, and on further income from the regular use of the additional wires that would be shortly put in operation. He held in his hand a statement of the number of messages which had been sent by the company during the last four weeks, since the more distant portions of the line had come into use. He found that during the past four weeks the company had forwarded 50,000 messages, and that during the corresponding period of the preceding year they forwarded 14,500. At that time last year they had in operation 370 miles of line, and 3,020 miles of wire, and now they had 1,305 miles of line, and 7,500 miles of wire. Now if they allowed the same increased proportion of messages to take place for the additional mileage about to be brought into operation by the company, if the number of messages increased in a similar ratio to what had been experienced hitherto, the result would be that the number of messages transmitted would amount to 77,469 per four weeks, or twenty-four working days. By adding to that number 15 per cent. to bring the messages into shillings, because they found that there was a sufficient number of messages longer than twenty words to make 15 per cent. a fair average, a result would be obtained of 88,000 shillings for four weeks, and multiplying that number by thirteen—the number of four weeks in a year—the result would be 1,141,800 shillings for the year, or £57,000 per annum. He had also another statement before him relating to the expenses of conducting the operations of the company. With the increased mileage the cost would be £31,919, thus leaving a large surplus to pay interest upon debentures, upon bonds, and a 10 per cent. dividend to the shareholders. Now, to give the meeting some conception of the way in which the expenses had been made up, to show the shareholders in fact that the directors had made a most ample allowance for all the probable expenditure, he would lay before them a few of the items making the total which he had mentioned. For advertisements the sum of £200 was put down; they anticipated that the cost of advertisements would come to £200. Now he thought they would all allow that £200 per annum was a large and liberal allowance for advertisements. For postages and stationery—and they all knew that postage was very cheap—they put down the sum of £400 per annum, as the probable cost under this head. For printing and stationery they put down £2,500. They all knew what a great quantity of books could be purchased now, including payment to authors, for £2,500, but they had put down the charge for printing and stationery as £2,500, and, including £1,000 to the directors, the whole of the items set down as expenses amounted to £30,919. Now, if they deducted £30,919, the estimated amount of expenses, from £57,000, the estimated amount of income, a sufficient margin was left to pay all claims and a good dividend, and he believed—he did most thoroughly believe, for he had carefully analysed the whole of the details—that when they met there that time next year they would find the anticipations which he had expressed fully realised, and that the number of messages transmitted by the company would be what he had stated. There was another point to which he desired to call the attention of the shareholders, and that was to the system or principle on which the company had been established; namely, the low, uniform charge of one shilling for messages of twenty words. From an account furnished to him he found that the number of messages which had been forwarded to their most distant opened station, namely, Glasgow, which was opened sixty-five days ago, was 11,545; they had increased since the commencement; the messages had now increased something like 50 per cent., but, taking the sixty-five days, the number of messages transmitted was 11,545, or at the rate of 177 per day, or 1,062 per week. Adding to this amount 15 per cent. for messages above twenty words, and the result would be an income of £60 12s. per week from Glasgow. The cost of the office at Glasgow, including salaries of clerk and messengers, was small, amounting to £12. It will be easily seen from this that a large margin was left to meet a dividend, and to cover any extraordinary expenses. Now, applying the shilling principle to short distances, and taking the case of Northampton, it appeared that in sixty-five days the number of messages forwarded was 454, or, allowing the addition of 15 per cent. for messages above the shilling charge, equal to a revenue of 48s. per week, but, inasmuch as the rent of the office and salaries of clerks and messengers amounted to 42s. per week, there was no profit; the balance of 6s. would not pay for current and extraordinary expenses. The importance of a low uniform charge to large places had

been proved, and what was the remedy for the state of things at Northampton? There were two courses open to them in cases of this kind; and the first they had adopted, which was the only one they could adopt. If they were to have retained the office, clerk, and messengers, they could not have taken a sufficiency to pay for dividend, and they were also certain it was the most prudent course, having reference to the experience of foreign companies, not to raise the charge. Under those circumstances they employed a tradesman in the town to do the business for the company upon commission, and he paid to the company a considerable amount of profit or balance. The other course was to carry out the work in conjunction with the other two companies; that was that one office, one clerk, and three messengers should do the work of the three companies. The first course, however, was approved and adopted. When the shareholders got no dividend on money invested in an undertaking they must naturally become dissatisfied; it was not to be supposed that shareholders would continue to supply the public with accommodation unless they got a dividend upon their capital. From the experience which had been already gained there was no doubt it would be found that the shilling scale, instead of being inadequate to pay the expenses of the undertaking, would be found not only quite sufficient for that purpose, but in time that charge, with due regard to the interests of the shareholders, might be very considerably reduced. He started with saying that he thought he had fair grounds for congratulating the shareholders on the present condition and future prospects of the company. They would shortly have a line of 9,300 miles of wire, the trunk line could be put up at a considerably diminished expense, and notwithstanding the cost of obtaining the Act of Parliament, and all the extraordinary expenses they had to encounter, they found that their property was in the most efficient and substantial condition at a moderate cost. They had their line at a less cost than that of the other two companies, and at remarkably less than the cost of the line of one of the other companies. Their line, too, was in the most effective and excellent condition, the instruments were of the most improved and satisfactory character, and the line possessed the most perfect insulation, thanks to the indefatigable exertions of their secretary and manager, to his useful inventions, and unceasing anxiety to promote the interests of the company. (Hear.) To show the efficiency of their line he might mention that one of their clerks, Miss Foster, one day lately forwarded and received 101 messages between the Stock Exchange of Manchester, and the Stock Exchange of London, in less than one hour—the whole of the work being performed with her own hands. (Hear, hear.) Under those circumstances he thought they might fairly congratulate themselves on the condition in which they were, and on the future prospects of the company. (Hear.) He needed not to detain them any longer with further observations of his own, but he should be glad to answer any questions which any shareholders might think proper to put to him. But before sitting down he should like to say a word or two respecting the two other companies. There had been differences between them; but he attributed any trouble and inconvenience that had been suffered from the other companies, not to the directors, who were not so much to blame, but to some of their officers. There had been occasions when they had had to refer to the other two companies in not very refined terms, but now they showed the most kind and considerate treatment to this company in every way. (Hear, hear.) If they could do anything to forward its interests without damaging their own, they were very glad to do it. He thought it right to make these remarks, after what might have taken place. (Hear.) He begged, in conclusion, to move that the report and accounts be received and adopted.

Lord ARTHUR CHURCHILL, M.P., seconded the motion. The chairman had gone into the most satisfactory details as to the present position and future prospects of the company, and he could only add his testimony to what really was the case, that there was every prospect of the company being, by next year, in a position to pay a very handsome dividend to the shareholders. They all knew the difficulties with which they had had to contend, and which they had happily been able to surmount. It was thought that it would be advantageous to the company to have subscribers in the country, and he was engaged with Mr. Andrews, the secretary, and others, two years ago, in travelling the country for the purpose of raising subscriptions in the various towns, and thus to make this a consumers' company. (Hear, hear.) Now they had, in the large telegraphing towns 1,143 subscribers, 1,000 of whom were resident manufacturers and persons in business who used the wires of the company in the carrying on of their business operations. That gave the company a status in the country which they should not otherwise have attained, and insured the property of the undertaking. The shilling system, which had been largely carried into practice, admitted still of very considerable increase and extension. That system had promoted telegraphy to a very great extent, not only in the business of their own company, but in the increase of the dividends other companies were likely to pay. The shilling principle admitted also of a constant growth; there was a natural increase of business from the facilities which the system afforded to all classes to send messages throughout the country. In foreign countries where a uniform rate of charge had been established the result of the system was very satisfactory. In France, for instance, the increase of messages by adopting the uniform franc system was 198,259 messages over the previous year, which likewise exhibited an increase over the year preceding. That showed that the increase was one which was constantly growing. And the system was founded on the uniform postage principle, which had succeeded so remarkably in our own country, as shown in the revenue of the Post Office department. And there was no telling to what extent the cheap telegraph system might not be carried, provided always that the line and system of telegraphy were kept in good order, so as to ensure a perfect system of communication. In his opinion their own company had got an excellent line and apparatus of the best description—apparatus of the most practical character. They had got Siemens' improved instruments, and there were other instruments of the most approved character used by the company. That being so, and their lines of telegraph having been constructed on the very best principles, there was every prospect of their being able to maintain that position which they now occupied in the telegraphic world. The directors gave every credit to their officers and clerks, who were most active and energetic in the discharge of their duties and in their endeavours to promote the interests of the shareholders of the company. (Hear, hear.) Under those circumstances there was every probability of the company proving a great success. Such being the case he had great pleasure in seconding the motion proposed by the chairman.

Mr. CREMONINI said he wished he could, like the last speaker, follow the chairman in his congratulations on the present condition of the company. He should have had a point of congratulation if the directors had shown in the statement submitted to the shareholders, a recommendation to declare a dividend. A dividend was what the shareholders looked for. It was all very well for the directors to present to the shareholders good appearances, and to talk of the future prospects of the company, but it was not so pleasant to the shareholders to have no dividend. He was totally ignorant of the deed of settlement of the company up to the present day. From his experience and connection with other companies he thought it was the duty of the shareholders to make themselves acquainted with the deed of settlement. He found by the deed of the company that the qualification of a shareholder to become a director was that he held 500 shares. Might he ask if the deed had been altered?

The CHAIRMAN.—No; the deed had not been altered.

Mr. CREMONINI then asked if each director held 500 shares of the company.

The CHAIRMAN.—There was not a director who did not hold more shares than the number requisite for qualification. He himself held more than double that number.

Mr. CREMONINI was glad to hear that. He hoped the directors would excuse him putting those questions, but he thought the shareholders ought to inform themselves respecting the affairs of the company. How many directors are there?

The CHAIRMAN.—There are eleven directors in the company.

Mr. CREMONINI was of opinion that £1,000 was a very handsome sum to be divided amongst eleven directors.

The CHAIRMAN.—The directors had reserved to themselves £1,000, but that matter was to be submitted to the shareholders.

Mr. CREMONINI.—May I ask what is the salary of the secretary?

The CHAIRMAN said the secretary did not receive so much as he was entitled to, or as he (the chairman) hoped he would receive when the company was in a more prosperous condition.

Mr. CREMONINI thought it nothing but fair that they should have information on such matters, and he thought any shareholder had a right to put such questions. As a shareholder he thought he had a right to put the questions which he had done, and he should be very happy if the shareholders could meet the directors more frequently than once a year.

The CHAIRMAN.—Before the meeting broke up it was his intention to propose that they should have a meeting every six months, and the directors expected to have to recommend a dividend at the end of the next six months.

Mr. CREMONINI.—I should like to move a resolution that we should hold the meetings half-yearly.

The CHAIRMAN would be glad to hear Mr. Cremonini propose such a resolution when the usual business of the meeting had been disposed of.

Mr. CREMONINI said he resided in a town in the heart of the iron trade containing many thousands of inhabitants; he lived at Bilston, where they had not the advantage of telegraphic communication, but it was a locality which ought to have the benefit of the telegraphic wires. Then, again, there was Wednesbury, a town of the greatest importance to the iron trade, but which, like its neighbouring town, Bilston, was without telegraphic communication. Now he thought that the town of Wednesbury, as well as Bilston should have telegraphic communication. If any of the inhabitants had to send a message to London by way of Wolverhampton or Birmingham, it cost a great deal more than it would do if there were stations at the towns he had mentioned, namely Bilston and Wednesbury. It would promote the convenience of the inhabitants, and further the interests of the company to extend their wires to these towns. He believed that their secretary, Mr. Andrews, had done all in his power to promote the welfare of the company. Whenever he (Mr. Cremonini) had written to him on business connected with the company and for information, the secretary had answered his letters promptly and in the most gentlemanly manner, and, if he found that the secretary had not a sufficient salary, when the company paid dividends he should be the first to propose that his salary should be raised. But while on this subject he would say that a great mistake had been committed, either by the secretary or the clerks, in not letting the shareholders have the report before the day of the general meeting of the company. He, like the other shareholders, came to the meeting in

ignorance, blindfolded as it were, not having had a copy of the report until he reached the place where they were assembled. Now, he said that the report ought to have been in the hands of the shareholders at least a week before the meeting, so that they might know how matters were going on, and come prepared to take part in the proceedings. (Hear.) He was a shareholder of paid-up capital in advance, and he called on the chairman to see that there was justice done. Wherever he had prepaid money he had always received interest; and unless it could be shown that this company could not make the payment, he thought he was entitled to interest on the money he had prepaid. He should, when the proper time arrived, move a resolution for holding the general meetings of the company half-yearly, so that the shareholders might have information concerning their property as soon as possible. He wished to say that though desirous of obtaining information by the questions he put, he had no hostile feeling in doing so, but on the contrary he should do all in his power to promote the interests of the company. (Hear, hear.)

The CHAIRMAN said the directors had not overlooked or forgotten the towns of Bilston and Wednesbury, which they looked upon as being likely to prove important telegraphing places, but they were in the habit of first asking for subscribers in the towns in the country to be embraced in their telegraphic communication, giving the subscribers stamped bonds, bearing 7½ per cent. interest, and the directors would, in the usual way, ask the inhabitants of Bilston and Wednesbury for subscriptions. The system of getting subscriptions formed an intimate connection between the towns and the company; it made the towns tied to them, and that had been a great strength of the company hitherto. As regarded the general meetings and the sending out of the report to the shareholders some days before the meetings were held, hitherto a difficulty had been experienced in getting the report ready in time to be so sent out. According to their deed the general meeting must be held in July, the accounts were made up to the end of June, and looking at the extensive ramifications of the company there was considerable difficulty in getting all the accounts prepared and made up in time, but when they had half-yearly meetings they should have time for the preparation of the financial statement to be laid before the shareholders, and there would be time to send out the report to the shareholders a week or so before the day of the meeting. As regarded the claim made by Mr. Cremonini, for interest on prepaid money, he thought they must decide against him for the present. The shares which that gentleman possessed were shares paid in part payment for work done by some of the contractors, to bear dividend along with the shares of the company, so that the money advanced was not advanced with the condition that it should bear immediate interest. A portion of work done was paid for so much in money and so much in shares, to bear dividend when dividends were declared. But they could not pay dividend upon those shares until a dividend was declared amongst the whole of the shareholders. However the question would be submitted to the solicitor of the company for his opinion.

Mr. CREMONINI.—If the directors issued those shares in exchange for work done for the company, he bought the shares with their sanction, and they admitted him a shareholder. And he applied for interest on prepaid money, which he said he was entitled to. If they issued shares to parties that were doing contract work for them, they ought to have pledged them not to part with those shares until such a time as dividends were paid. But if they consented to take the transfer, he said he had a just claim to demand interest on the prepaid capital; he had a right to be paid interest.

The SOLICITOR to the Company.—Under what document do you make a claim for dividend?

Mr. CREMONINI.—I claim a dividend, you admitting me as a shareholder of paid-up capital.

The SOLICITOR wished to know under what document Mr. Cremonini claimed. Unless he had a preferable claim it would not be just for the directors to pay him dividend, and not the other shareholders?

Mr. CREMONINI said he claimed because he was a shareholder of prepaid capital.

The CHAIRMAN.—The question will be submitted to the solicitor for consideration.

Mr. CREMONINI remarked, in reference to the obtaining of subscriptions in the two towns to which he had referred, that if they were to solicit subscriptions at Bilston and Wednesbury, he questioned if they would succeed, for they were near one of the townships already. But he was sure the feeling of the inhabitants was in favour of giving the business to the United Kingdom Company in preference to any other company, because it was the first to reduce the charge of messages.

The CHAIRMAN said the requisite inquiries and investigations would be made at Bilston and Wednesbury respecting the establishment of telegraphic communication at those places. The claim set up for interest by Mr. Cremonini would also be inquired into.

Mr. GORING saw that there was a large item put down for law expenses. Then there was the case of Allan—how was that settled?

The CHAIRMAN said they had had very little law expense; he supposed that £50 would pay the whole of such expenses during the last half-year.

The SOLICITOR.—Half of that sum.

The CHAIRMAN.—They had not been expensive under the head of law charges. He thought there was nothing more to be avoided than a law bill, and they had not had much outlay on law. As to the case of Mr. Allan, the amount was incurred the previous half-year. Mr. Allan, who was formerly the electrician of the company, brought an action against them. The company thought that Mr. Allan had not the slightest claim morally upon them, and that he had not the thousandth part of the scintilla of a claim legally upon them. And Mr. Allan having thwarted them in every way, and given them great annoyance, the directors came to the conclusion that the claim he set up was one which they should resist to the utmost, and were prepared to do so. But on the very morning of the trial Mr. Allan's own counsel went before the judge, said he thought he had no case, and withdrew the record. Though the company were put to an expense in preparing for that trial, they had a claim for the recovery of the whole of it upon Mr. Allan.

In answer to Mr. GORING, who drew attention to the matter,

The CHAIRMAN said that there were certain items entered under the law charges which ought not strictly to come under that head. That would be avoided in future.

A SHAREHOLDER said he thought it was premature for the directors to reserve for themselves £1,000 at the present time.

The CHAIRMAN.—We will submit the matter to the shareholders at the end of the next six months, if you like.

A SHAREHOLDER.—I suppose that this is the proper time, as it is remuneration for the past twelve months.

The CHAIRMAN.—Well, we have not taken it yet, I can tell you.

A SHAREHOLDER.—But if we pass the report and accounts it will give you power to do so.

The CHAIRMAN said the directors would pledge themselves to the next meeting not to appropriate anything to themselves until they had submitted the subject to the shareholders.

Captain WASEY inquired what position this company held in reference to Bonelli's opposing line at Manchester, which was conducted on the sixpenny principle?

The CHAIRMAN said that that line was given up at the present time.

In answer to a question by Mr. CREMONINI,

The CHAIRMAN said the directors had taken during a portion of the time of the operations of the company the amount allowed by the deed of settlement, and they thought they were entitled to it. The directors held close upon 1,200 shares each in the company, the whole of them were paid-up, they had received no interest, and were a considerable amount out of pocket in travelling expenses; so that they had, up to the present time, acted according to the deed of settlement. But the directors had come to the resolution not to take the proposed remuneration of £1,000 until the subject was submitted for approval to the shareholders.

Mr. CREMONINI was very glad to hear that the directors had such a large interest at stake in the company, and he hoped the anticipations which their worthy chairman had expressed that day would be fully realised. He was very glad the chairman coincided with him as to the propriety of holding half-yearly meetings, a subject upon which he should presently propose a resolution.

The CHAIRMAN then put to the meeting the motion that the report and accounts be received and adopted, and it was unanimously agreed to.

The CHAIRMAN then moved the second resolution:—"That James Nugent Daniell, Esq., Edward W. H. Schenley, Esq., and George Virtue, Esq., be re-elected directors of this company."

Mr. ROBINSON seconded the motion, which was carried *nem. con.*

The CHAIRMAN moved the next resolution:—"That Percy Stace, Esq., and Theodore B. Jones, Esq., be re-elected auditors of the company."

Mr. GORING seconded the motion, which was unanimously agreed to.

Mr. CREMONINI then moved:—"That in future the general meetings of the company be held half-yearly, instead of yearly." He hoped, and had no doubt, that the proposed change would have a beneficial effect, inasmuch as each shareholder would take greater interest in what was being done by the company. He thought that their company was now one of some importance, and that the shareholders ought to meet oftener than at present, so that they might receive accounts respecting the state of the company, and what were its operations and success. He hoped sincerely that the anticipations uttered by the chairman would be fully realised, and begged to move that the meetings of the company be held half-yearly instead of yearly.

Mr. EDWARD W. H. SCHENLEY seconded the motion.

The CHAIRMAN said it might not be quite regular to call the meeting a half-yearly one, but it could be called a general or extraordinary meeting of the shareholders of the company, or something of that kind. In this way the shareholders might be called together within seven months of the present time, and he hoped they might then be in a position to declare a dividend. The directors would also make arrangements, so that the report and statement of accounts should be forwarded to the shareholders as many days before the meeting as possible.

Mr. CREMONINI's motion was then passed unanimously.

The CHAIRMAN said he had to move a vote of thanks to their very talented and able secretary and manager, Mr. Andrews. From what had already taken place there could be no doubt of the success of this company; and when it became an established fact, with payment of 10 per cent. dividend, as well as the apportioning of back dividends on paid-up money, they should keep in mind at that time the gentleman who had done so much for them (Mr. Andrews), and take care that at that time there should be some acknowledgment of his superior merit and extraordinary talents. He had much pleasure in proposing a vote of thanks to Mr. Andrews, the secretary and manager.

MR. CREMONINI had much pleasure in seconding the resolution. Of course in any new undertaking the responsibility rested mostly on the officers of the company who had the principal management. We live in a wonderful age, and the electric telegraph aimed at, and undoubtedly had already achieved, great things, though still greater would, there was no question, yet be accomplished. He had noticed that their worthy secretary was a gentleman well qualified to manage the affairs of the company, and he did hope for his honour and credit's sake that the remarks of the chairman would be realised. At the same time he was not so sanguine as to expect a 10 per cent. dividend at once; he would rather hold up his hand for a 5 per cent. dividend to begin with. If they could pay their way—if they maintained a solvent and independent position before the public—the public would support them, and they should be able to show to the public that they were at least equal to any other company.

The motion was carried amidst applause.

Mr. ANDREWS, the secretary, thanked the meeting for the very kind and flattering vote of thanks which had just been passed. That vote could not be meant for himself only, but to include all the other officers of the company, who all co-operated to the greatest extent. They had not only worked hard and done their duty, but they had done more than their duty, and had worked with the greatest enthusiasm for the company. More especially was this the case with their engineer, Mr. Powell, who had laboured night and day, and done his work in an excellent and efficient manner, and generally speaking the directors and shareholders had reason to be satisfied with the exertions of their officers. He had, therefore, to thank them, not so much for a vote of thanks to himself, but to him as the representative of the officers of the company in general, in which form he had very great pleasure in receiving and thanking them for the compliment.

Mr. HOOD moved a vote of thanks to the chairman and directors generally.

The motion was seconded and carried by acclamation.

The CHAIRMAN acknowledged the compliment.

The meeting then broke up.

REPORT OF THE DIRECTORS OF THE ELECTRIC AND INTERNATIONAL TELEGRAPH COMPANY.

THE prosperous condition of the country has caused great activity in every branch of the Company's operations during the half-year.

Notwithstanding the numerous local reductions in rates which have been made from time to time, the internal receipts have increased, and the new circuits and stations which have been opened have contributed to this result; but the large addition to the revenue which has accrued during the last six months is mainly due to the great expansion of the Continental traffic arising from the constantly widening area of the telegraphic field throughout Europe.

The gross income of the Company for the half-year ending 30th June, 1864, amounts to £136,473, and is in excess of that for the corresponding period of 1863 by the sum of £19,263.

The working charges incurred in earning this revenue, including the interest of the debenture debt, and the sum voted by the general meeting to the late secretary, amounts to £87,643, or £9,495 more than in June, 1863. There is consequently an increased profit over the return of that period of £9,679, and the net income of the half-year, after making every provision, amounts to £48,830.

The proprietors may reasonably expect to participate in the success which, from the causes assigned above, has attended the undertaking; and having due regard to their established policy of applying a fair portion of the earnings to the reserve fund, the directors feel warranted on the present occasion in recommending a dividend of £4 per cent. for the half-year on the stock, and on the new shares £5 paid up. This appropriation will absorb £38,995, and leave a balance of £9,835 to be carried to the trust fund.

This fund, with its accumulated interest, now amounts to £29,188 4s. 3d., and the above addition will increase it to £39,023 6s. 9d.

The Electrician's report appended hereto will satisfy the shareholders that no relaxation has taken place in the directors' determination to maintain every portion of the system in the highest state of efficiency. They are daily more impressed with the necessity of attending carefully to this essential condition of the Company's well-being. Surrounded as they are by new candidates for the public favour, they can only retain and extend the public confidence by performing the service in the most complete, accurate, and rapid manner of which the telegraph is capable; and every invention having this object is examined by them with a view to its practical application, if it affords reasonable ground for expecting an improvement. The accounts which they have now the pleasure of submitting afford some evidence that the public, by their continued and increasing support, appreciates the efforts made to maintain a superiority over their rivals.

Following the course which for many years they have steadily pursued, the directors have made a variety of modifications in their tariff during the half-year, as they found that they could do so with a fair regard to the interests of the shareholders; and although the first result of all such reductions is necessarily to check the receipts and increase the working charges, the board is strongly impressed with the conviction that a judicious periodical revision, as circumstances permit it, must, by associating the public to some extent in the success of the undertaking, contribute to the permanent prosperity of the Company.

ROBERT GRIMSTON, Chairman.

Report of Mr. Cromwell F. Varley, Electrician to the Company.

Gentlemen,—I have much pleasure in stating that your circuits continue in the same excellent order as mentioned in my last report.

The two wires in the Lowestoft-Zandvoort cable, which were injured during the heavy gales in December last, were successfully repaired on the 28th March. Your other cables have worked without any interruption during the past six months, and their insulation remains unimpaired.

The additional wires connecting London with Manchester, Derby, Leeds, Newcastle, and Edinburgh, and the new wire between Edinburgh, Dundee, and Montrose, have been completed, and are now in full and efficient operation. An additional wire has also been erected between London and Epsom.

The renewal of your line on the west coast, between Glasgow and Lockerbie, is rapidly progressing, and will shortly be completed; and at various other places, where weakness had become apparent, the lines are being renewed in the most approved manner.

The last section of your underground wires between London, Manchester, and Liverpool, viz., between Colwich and Rugby, is almost entirely replaced by overground wires, and before autumn sets in this communication will be equal to any in Great Britain.

In June the new pneumatic system was completed and put into operation between the various stations in Liverpool. This is working in the most satisfactory manner.

The new central station in Manchester has been opened, and is in full work. The construction of the pneumatic system to connect it with the branch offices is progressing rapidly.

In addition to the works mentioned above, the following have been completed during the present half-year:—The erection of the telegraph on the Broughton and Peebles branch of the Caledonian Railway, on the Gosport and Stokes Bay line, and on the Merthyr, Tredegar, and Abergavenny Railway, between Brynmawr and Tredegar. An additional commercial wire has also been completed between Plymouth and Truro, and between Falmouth and Penryn.

The following works are in progress:—The erection of an additional wire for commercial purposes between Liverpool and Glasgow. The erection of the telegraph on the following lines:—The Hertford, Luton, and Dunstable Railway, the South Leicestershire Railway, the Farringdon Railway, the Isle of Wight Railway, the Inverness and Ross-shire Extension Railway; the Eccles and Wigan line of the London and North Western Railway, and the erection of additional wires for train signals on the most important sections of the same railway.

The figures below show the increase of your system:—

	Dec. 1863.	June, 1864.	Increase.

ROBERT GRIMSTON, Chairman.
H. WEAVER, Secretary.

HALF-YEARLY MEETING OF THE ELECTRIC AND INTERNATIONAL TELEGRAPH COMPANY.

On Wednesday afternooon the thirty-seventh half-yearly ordinary general meeting of the proprietors of this company was held at the company's offices, Telegraph-street, Moorgate-street, to receive the directors' report and statement of accounts, and for the transaction of the ordinary business of the company. At the close of the ordinary meeting a special general meeting was held for the purpose of considering and determining on the claims of Mr. Fourdrinier, the late secretary, to a further grant of money in addition to that voted at the last half-yearly meeting.

The following directors were present:—The Hon. Robert Grimston, chairman; Mark Huish, Esq., W. F. Cooke, Esq., Frederick N. Micklethwaite, Esq., W. H. Smith, Jun., Esq., and Richard Till, Esq.

The chair was occupied by the Hon. Robert Grimston, chairman of the company.

The Chairman, in opening the proceedings, called on the secretary to read the advertisement by which the meeting was convened.

Mr. Weaver, the secretary, accordingly read the advertisement.

The Chairman said he had to affix the seal of the company to the register of shareholders.

The seal having been affixed,

The Chairman said it was usual to take the report, which was in the hands of the shareholders, as read; would they now have it read by the secretary, or take it as read in the usual course?

The meeting decided to take the report as read.

The Chairman said he need hardly remind gentlemen present of the policy which had been pursued by this company for nearly seven years. Instead of striving after high dividends they had rather tried to strengthen the position and consolidate the property of the company, and in so doing they had from time to time been enabled to make numerous improvements and even additions to the property, and in their turn those improvements and additions had added to their revenue, so that during the period he spoke of—about six years and a half—their income had increased £96,000 a-year. In fact, the whole system worked in a circle. The more money they spent upon their lines the more money their lines would earn. For instance, if they took the cable that they last laid to the Continent, the cost of that cable was borne entirely out of revenue, and that cable every half-year brought back in revenue somewhere about 25 per cent. of its original cost. Now he could well understand many sensible persons would say that, with a policy that had succeeded so well, why should they not be content?—why should they not leave well alone? But there must be bounds even to prudence; there must be some limit; there must be moderation even in moderation itself. (Hear, hear.) And even if they were desirous of doing so, they could not gainsay those figures which had been presented to them. They had not neglected the maintenance of their property; but, on the contrary, they had maintained all their lines in the most efficient condition; they had proposed to lay by a sufficient sum for reserve, and yet there remained out of the net earnings for the half-year a sum more than sufficient to pay the dividend they had been accustomed to receive. That money belonged to them—to the shareholders—and the directors proposed to divide it, and that they raise the dividend from 3½ per cent. to 4 per cent. for the half-year. (Hear.) Now, he trusted that gentlemen would look at this in a business-like manner, and that they would not think that this was their fixed income. They must recollect that dividends depended upon rates, and that rates depended upon circumstances—upon circumstances over which no mortal had ever control. And he hoped that the shareholders would look upon the income of the past half-year as an exceptional income—in fact, as a sort of bonus they had received at the termination of an unusually prosperous half-year. The accounts spoke pretty plainly for themselves. On one side were increased rates, and on the other side were expenses attendant upon earning those rates, which are also necessarily increased. The percentage of rates was largely reduced; it was reduced nearly 3½ per cent., and certainly with an increased traffic a reduction ought always to be a matter of course. But it was not quite a matter of course when they came to consider that they had reduced their tariff to nearly every principal place in this kingdom. Some of those reductions had been forced upon them; for instance, they carried a message from London to Glasgow, a distance of 400 miles, for 1s. Now that was absurd. But other reductions had been made voluntarily, and they had to be well weighed and thoroughly considered by the board of directors; and he had no hesitation in saying that all those well-weighed and thoroughly-considered reductions would ultimately prove most beneficial to the company. (Hear.) There was a question he should have to say a few words upon hereafter, and that was with respect to the claims made upon the company by Mr. Fourdrinier, their late secretary. Notice had been given that at the close of the present meeting a special meeting would be held for the purpose of considering those claims, and then he should have an opportunity of saying a few words on the subject. He had now great pleasure in moving that the report and accounts be received and adopted.

Mr. Mark Huish, deputy chairman of the company, had great pleasure in seconding the motion.

The Chairman put the motion to the meeting, and it was carried unanimously.

The Chairman moved that a dividend at the rate of 4 per cent. for the half year ending 30th June, be declared on stock, and on the new shares, five pounds paid up, to be paid out of the profits of the company.

Mr. Mark Huish seconded the motion with great pleasure.

The Chairman put the resolution, and it was passed *nem. con.*

This concluded the business of the ordinary general half-yearly meeting.

The meeting then resolved itself into a

SPECIAL GENERAL MEETING.

The Case of Mr. Fourdrinier.

This meeting was held for the purpose of considering and determining on the claims of Mr. Fourdrinier, the late secretary, to a further grant of money, in addition to that voted at the last half-yearly meeting.

The Chairman said, during the time he had had the honour of a seat at the board of directors, what with an indulgent proprietary and a united board, and generally pretty prosperous seasons, he allowed that he had had a great deal of pleasure in assisting in carrying on the affairs of this company. He did not say that occasionally circumstances had not arisen to vex or annoy one; but still, upon the whole, the smooth had very much predominated over the rough. (Hear, hear.) However, at their last half-yearly meeting a circumstance arose which gave considerable annoyance to his brother directors and himself. As the affairs of the company had increased to such an extent—they had increased to such an extent as to go beyond the powers and scope of the gentleman who had been in their service as secretary for fifteen years (Mr. Fourdrinier)—the board felt that they required a younger man, and the infusion of fresh blood into the company; and accordingly they appointed Mr. Weaver their secretary in the room of Mr. Fourdrinier. That was a step which he was quite sure all the shareholders and the board of directors had reason to congratulate themselves upon, for it had been a most successful step. (Hear, hear.) But still, at the same time, in getting rid of one servant and installing another in his place, the board thought they should only be doing an act of justice

and policy in giving the former some remuneration for his past services. The last half-yearly meeting was but very thinly attended indeed, and some opposition arose on the part of some of the shareholders to the proposition of the board. And though it was in the power of the directors with their own personal votes, to carry the motion they had proposed, they did not, however, intend to use the proxies which were entrusted to them by a number of shareholders, though it was in the power of the directors, by their own personal votes, to carry their proposition; they, however, thought it more decorous to bow to the decision of the meeting, and they did so. At the last meeting the resolution agreed to was, that the sum of £1,000 should be awarded to Mr. Fourdrinier. Now, when he told them that Mr. Fourdrinier could have claimed from the company a year's salary of £750, it would be seen that the vote of £1,000, come to at the last meeting, actually gave to their late secretary only £250. (Cheers.) And that remuneration was at the end of fifteen years' faithful and upright service, and those years the best years of the gentleman's life. Surely it was not to be wondered at that the gentleman should say that that provision was one that was inadequate. But after the meeting he (the chairman) found that the resolution awarding Mr. Fourdrinier £1,000 did not give satisfaction. It was not satisfactory to a number of the proprietors, who said they did not approve of it, and thought that it was unworthy of a great company. (Hear, hear.) They also said that the motion was carried by surprise.

A SHAREHOLDER—No, no. (Cries of "Yes," and "Order.")

The CHAIRMAN (in continuation)—He was only telling them what was told him, and he might have put it in stronger language. They said that the motion was a very unsatisfactory one, that it had been carried by surprise, and that the directors should have given notice to the shareholders that the subject was to be considered at the meeting. And accordingly the directors had given due notice that the subject would be brought before the present meeting, so that gentlemen if they thought fit might come forward and express their opinion upon it. (Hear, hear.) And in order to put the question into shape, he now moved that the sum of £1,000 be paid to Mr. Fourdrinier, in addition to the sum voted at the last half-yearly meeting.

Mr. W. F. COOKE said, although he had not been called upon, he had great pleasure in seconding the motion proposed by the chairman. Mr. Fourdrinier was a most faithful and upright officer of the company, to which he had remained constant under circumstances of great temptation. During the time he was their secretary other companies were springing up, and they tempted the officers of this company to leave by offering higher sums as salaries. Considerable advances on their salaries were offered to them to join other companies, and, although they were receiving good salaries, with the prospect of an increase, yet some were fairly tempted away from them. But notwithstanding the temptations held out, Mr. Fourdrinier was always firm and staunch to the company; he did not think that anything would have drawn him away from them. His (Mr. Cooke's) belief was that Mr. Fourdrinier was a really honest, upright, and conscientious man. (Hear, hear.) He was a faithful servant to the company, to which he devoted his time. He did not raise the question of his talents, about which, perhaps, a difference of opinion might exist; but he spoke of his staunchness and fidelity to the company. In the midst of temptations to withdraw him from them, he stuck to the company. He hoped there were others who, like him, would be faithful to the company. He had much pleasure in seconding the motion of the chairman, which, in an exceptional and highly-deserving case like the present, ought to be carried. Mr. Fourdrinier entered their employment when somewhat advanced in life, and might fairly be expected to retire after serving fifteen or twenty years. It was found that as their business increased so much they should have younger men in their offices, and Mr. Fourdrinier retired without making any obstacle to the arrangements proposed to be carried out by the board. The chairman had spoken of Mr. Fourdrinier in a favourable manner, and their late chairman, Mr. Stephenson, had he been present, would have done the same; and so also would another chairman, had he been here, he meant Mr. Ricardo, who might be considered the founder, the great manager, and the man who, for years, gave life and energy to the company. If they would allow him, he would read some extracts from a letter of Mr. Ricardo, in which he referred to the character and services of Mr. Fourdrinier. The extracts were as follows:—"I cannot consider myself fairly out of the wood till a permanent chairman is appointed, but my emancipation from the labour and anxiety of the thankless office I have held for ten years does seem possible, notwithstanding the difficulty to enable me disentangling myself from this thing. It is, however, impossible that I can leave the chair of the Electric Telegraph Company without a most full and ample acknowledgment of the great assistance that I have received from you in the administration of the affairs of the company. The industry, perseverance, and talent which you have shown on every occasion, in which such qualities are demanded, have relieved me of such a load of anxiety and perplexity, as it would have been difficult for me to support, while the complete and unrestricted confidence which I reposed in your integrity enabled me cheerfully to accept any financial responsibility which fell upon me, and I feel the assurance that my honour and reputation are safe in your hands. I have to thank you for many valuable suggestions for the more efficient organization of all the departments under your control, and for the prompt and efficacious manner in which you willingly carried out my views and projects, and also for on many occasions showing me their inutility or impracticability. It is not the way of the world, nor do I expect that any exertion of yours or mine in a public capacity should be acknowledged or appreciated, but I think we shall always have some satisfaction in the associations connected with the difficulties we have encountered together, and, I may say, overcome together. And I, for my part, shall always take an interest in the prosperity of the undertaking, and my advice or assistance will always be at your command. I cannot conceal from myself that in the performance of my duty I have been compelled to make some enemies, but I hope that I have made many more friends, and amongst them all believe me that there is not one whom I value and respect, and whose regard I desire to retain more than yourself." Such were the sentiments of Mr. Ricardo. (Hear.) From the feeling that was expressed by the meeting before he ventured on reading the letter—it was almost unnecessary for him to do so; but he thought it was only an act of justice to Mr. Fourdrinier that it should be read (hear), and also an act of justice to Mr. Ricardo, to show that that gentlemen was always ready to acknowledge the labours of those who assisted him in carrying out his projects for the extension of telegraphic communication. Before sitting down he had much pleasure in seconding the motion of the chairman.

Mr. J. W. FRASER inquired how it was that the sum of £750 was due to Mr. Fourdrinier?

The CHAIRMAN.—He had a right to claim a year's salary of £750.

Mr. FRASER.—Had he not notice?

The CHAIRMAN.—No; he was discharged under peculiar circumstances.

Mr. FRASER only made these remarks because the chairman said £750 were due to Mr. Fourdrinier, and he was wondering how it was that sum was not paid.

The CHAIRMAN.—Under the circumstances of his leaving, a year's salary was due to him, but as the company chose to give him £1,000, Mr. Fourdrinier made no claim for the £750; so that in point of fact the company had really only given him £250. The whole of the circumstances connected with Mr. Fourdrinier's leaving the service of the company he could explain, but he did not think it was necessary to do so.

Mr. FRASER remarked that the first proposition made at the last meeting was to pension their late secretary, but that was objected to, as establishing a bad precedent. In the course of some further remarks Mr. Fraser was understood to object to the principle involved in the motion before the meeting, though he had no particular feeling in reference to this case.

A SHAREHOLDER thought that the sum of £1,000 ought to be given to Mr. Fourdrinier.

Mr. KIMBER said no doubt Mr. Fourdrinier had assisted Mr. Ricardo in the services he had rendered to the company. He believed that the question to be considered was not whether Mr. Fourdrinier was a good servant while in the employment of the company, and not whether he should be well paid for his work, because he had been paid, but the question was whether, after his services had been terminated by the board on behalf of the company, the company should be called upon to vote this £1,000 without any consideration —whether they were entitled to pay away this money which belonged to the whole of the shareholders. Now, he did enter his protest against such a proceeding. He did not wish to see any one underpaid for his services— he had had too many under him for years not to know that it was a good policy to pay servants well—but on behalf of the shareholders, though his own interest in the company was not so large as to make it a matter of importance to him, he protested against the motion. His opinion was that to carry the motion into effect was *ultra vires* of the board, and he therefore entered his protest against it. At the last meeting it was objected to the proposition then made that no notice of it had been given. Now that omission had been rectified. At the last meeting the sum of £1,000 was voted to Mr. Fourdrinier in lieu of a pension, which was considered objectionable in principle. The question was had they the power, after the termination of the services of their late secretary, to vote money to him? Now, he said they had no such power, and that if there was only a minority of one against it, it was in the power of that shareholder to take proceedings against the directors for assuming that they had authority to do so. He did not wish the company or the directors to get into difficulty. He did not raise this difficulty without due consideration, and in his opinion it was well founded. A word as to the £750 which it was said Mr. Fourdrinier might have claimed from the company. No doubt that gentleman might have claimed a year's salary if he was discharged from the service of the company without notice. But why did not the board retain Mr. Fourdrinier's services for the year; they might have retained them *quantum valeant*—they might have furnished him with something to do for the £750. He did not wish to pump the directors for the reasons why they discharged, without notice, Mr. Fourdrinier, and engaged another gentleman in his place; but he did not see why, after paying their late secretary £750 a-year, they should be called upon to give him £1,000. The directors might commit errors in judgment, but he did ask them to pause before entering on a course which would lead to great irregularities and illegalities.

Mr. GLASS thought this matter involved a very serious question. The shareholders left their property in the hands of the board, and he thought that from the report placed before them that day they must all come to the conclusion that their property had been thoroughly well managed. (Hear, hear.) And if any individual shareholder was to be at liberty to interfere with the board as to the way in which servants were dismissed or taken on, he thought the sooner the shareholders took charge of the business the better. (Hear, hear.) He did not inquire why Mr. Fourdrinier was dismissed; he presumed that there was good reason for it. He did not inquire

why he did not receive notice; he presumed that there was good reason for it. Mr. Weaver has been appointed secretary, and that appointment has given universal satisfaction. (Hear, hear.) He knew that he spoke the opinion of a great many when he said that the course proposed to be taken in reference to Mr. Fourdrinier was a correct one, and he was prepared to support the directors. He hoped that shareholders would consider the effect, the serious effect, of interfering with the directors in the steps they had taken. If their decisions were to be constantly subject to the approval of a general meeting of the shareholders, he thought their position would be anything but agreeable and pleasant. (Hear.)

Mr. Bocknell.—Is there any understanding of a pension or allowance beyond this £1,000?

The Chairman.—No, nothing beyond this £1,000.

Mr. Bocknell.—After a man had served the company so long and so well, after the testimony which had been borne to his character by the well-qualified dead, as well as the living, he thought they should not do otherwise than pay him well, and they ought not captiously to call in question the conduct of the men who were doing their best for them—the directors. (Hear, hear.) See how they were getting on, and look at other companies! They had directors who were willing to do all for them, and to serve the company in the best possible manner. Their late secretary was a useful and very worthy and efficient man, and he really did say that if a man had for fourteen or fifteen years served well in a high position, and had got the confidence of the directors and the company, perhaps £1,000 was really nothing more than what was due; and he hoped the little captious feeling in opposition to the directors would be put aside, and that they should, hearts and hands together, carry the motion.

Mr. Reid.—If this Mr. Fourdrinier was such an efficient and worthy servant, why was he discharged?

A Director.—He was not discharged, Mr. Reid.

Mr. Reid.—He was fifteen years in the company's service, but why should a man leave the company's service in the prime of life, when he might live other twenty years or more? Why should the directors discharge him, or order him to send in his resignation, because he believed that was the form of it, to make room for another? If that was the case, it would seem that the directors wished to get rid of the man, but had not courage enough to discharge him, and it was proposed that he should be pensioned for life. Perhaps the chairman could give them some information on the subject.

A Shareholder.—What is £1,000 to the company?

Mr. Reid was not saying anything about that. As to the letter which had been read, it was a letter by the dead bearing testimony to the character of the living; but he should be sorry to differ with Mr. Cooke upon the point of the propriety of reading that letter. Mr. Fourdrinier was incapable of conducting negotiations for the company; he was only fit to open letters. He would remind the meeting, moreover, that Mr. Fourdrinier came to the company in a state of semi-starvation. (Cries of "Shame, shame," "Stick to the point," and loud hissing.) It was the truth notwithstanding.

Mr. Cooke.—Perhaps you speak relatively; he was not in a state of semi-starvation.

Mr. Reid said the question he wished to get answered was, why was Mr. Fourdrinier requested to send in his resignation?

The Chairman.—Have you finished, Mr. Reid?

Mr. Reid.—For the present.

The Chairman.—You had better finish your address now.

Mr. Reid.—Oh, I have done.

The Chairman said in this matter the directors had taken the course which they considered best for the interests of the company. (Hear.) They had referred to their legal advisers, and it was found that the company had full power to do that which was now proposed by the motion before the meeting, and due notice had been given to the whole of the proprietors, so that it was in the power of every shareholder to attend the meeting, and express his opinion on the subject. He did hope that the gentleman who last addressed the meeting (Mr. Reid) had expended his venom at the last meeting against an inoffensive and faithful servant. (Hear.) He (Mr. Reid) read from a paper on that occasion certain matters that took place about fifteen years ago—long before he (the chairman) was a shareholder in this company, and long, probably, before many of them were shareholders; and after the meeting he (the chairman) made it his business to search into the archives of the company.

Mr. Reid rose to order. (Cries of "Oh, oh," "Chair, chair," "Order order.")

The Chairman, in continuation, insisted upon being heard. He was going to show the animus of that gentleman (Mr. Reid) against Mr. Fourdrinier, and he found from the minutes of the board why and wherefore he had such a feeling against Mr. Fourdrinier. (Hear, hear.) In the early days of the company the honourable proprietor (Mr. Reid) contracted to maintain the lines of this company. There were constant complaints made day after day that the lines were not properly maintained, and those unpleasant communications had to be made by Mr. Fourdrinier to the honourable proprietor. Now, the honourable proprietor so far neglected his duty that the board took the maintenance of the lines out of his hands, and he thereupon claimed several thousand pounds from the company. The board declined to pay him this money, and he thereupon commenced an action against the company. The company paid into court fewer hundreds than the honourable proprietor had claimed thousands, but he took the money out of court, and he dropped his action. (Laughter.) Now, the honourable proprietor at the last meeting stated that he prevented the company being robbed. He (the chairman) did not like the word "robbed," but that was the way in which he treated the company. Now, he thought the honourable proprietor ought to recollect that a man who lived in a glass-house should not be the first to throw stones. (Hear, hear.)

Mr. Fraser asked how it was, after the decision of the last meeting, that this question came up again. Many were under the impression that by the vote of the last meeting the question was settled.

The Chairman said the question had been brought before the meeting again at the request of several shareholders, and, amongst others, some of the largest shareholders of the Company; and, in fact, he had had an enormous number of proxies sent up to him for the purpose of being used at the meeting if necessary.

A Shareholder.—After the allegation which had been made by one of the speakers (Mr. Reid), that Mr. Fourdrinier was only fit to open letters, and incapable of conducting negotiations for the company, he said his experience proved that the contrary was the fact. Through the tact of Mr. Fourdrinier the company secured possession of a house, in which he (a shareholder) was interested, for a sum three hundred pounds less than he (a shareholder) thought they ought to have done; so that their late secretary, in this transaction, had, if he had injured him, done the company good service.

Mr. Reid said after the long story told by the chairman about something or other, he insisted on again putting the question he had done, but was called to order.

Mr. Reid said he wished to know why Mr. Fourdrinier was discharged?

The Chairman said he would give an answer privately.

Mr. Reid insisted on having an answer.

The Chairman said Mr. Fourdrinier was discharged because, in the discretion of the directors, they thought it would be advantageous to the company to obtain the services of Mr. Weaver, in the room of Mr. Fourdrinier.

The motion that the sum of £1,000 be given to Mr. Fourdrinier, in addition to the sum voted at the last meeting, was then put from the chair, and carried by a large majority, only a few hands being held up against it.

The meeting immediately afterwards broke up.

HALF-YEARLY MEETING OF SHAREHOLDERS OF THE LONDON DISTRICT TELEGRAPH COMPANY.

On Thursday afternoon the eleventh half-yearly ordinary general meeting of the shareholders of the London District Telegraph Company was held at the offices of the company, Cannon-street, for the purpose of receiving and considering the accounts, balance sheet, and report of the directors, and for the transaction of the general business of the undertaking.

There was a fair attendance of the shareholders, and the following directors were present:—Robert Taylor, Esq. (chairman of the company), who presided at the meeting; George Sheward, Esq., vice-chairman; Charles Kemp Dyer, Esq.; and Charles Reynolds, Esq.

The Chairman.—The secretary will read the advertisement calling this meeting.

Mr. Charles Curtoys, the secretary, read the advertisement by which the meeting was convened.

The report and statement of accounts, which had been some days in the hands of the shareholders, and which appeared in our last number, having been taken as read,

The Chairman said he was very glad to meet the shareholders that day, and he could have wished there had been a larger number present, because the time seemed to have arrived, or at all events seemed nearly to have arrived, when some anxiety was manifested as to when their receipts would meet the expenditure. The last time they met the directors contemplated or hoped for the fact that by the time the shareholders met this half-year they should be able to make both ends meet, and they would see by the accounts that the company had very nearly arrived at that position. They would find by reference to the accounts that for the half-year ending December, 1860, the deficiency was £2,168, and the next half-year ending June, 1861, it was £2,177 11*s.* 4*d.* From that time they had gradually gone on decreasing the deficiency, which they would find to be noted as follows:—after £2,177, it became £1,995, then £1,077, £894, £440, £796, and for this half-year the deficiency amounted to only £60 12*s.* Now, as to the fact of the public not so thoroughly appreciating the efforts of this company as he expected they would do, and as they ought to do, they could not help it; but still at the same time they should take courage from the past, and still look forward with confidence to the future, in the hope that when they met again there would be no deficiency. He hoped that the present was the last time they should meet together at which the question of deficiency would ever have to be entertained. He trusted that when next they met they would have the opportunity of congratulating themselves upon having realised a satisfactory surplus of income over expenditure. There had been a considerable increase in the number of messages. For the period ending June, 1863, the number of messages forwarded was 129,702, and for that ending June, 1864, 152,795. Taking hope from this, he fully anticipated that the present would be the last time they should have to meet to speak on the subject of a deficiency. When they looked at the amount of [illegible] this company had to raise, they would find that when they had [illegible]

corner, a very small sum would be sufficient to give the shareholders a dividend. Progressing next year as they had done during the past, he had no doubt that when they met again they should have the opportunity of congratulating themselves upon the fact that the directors had recommended the declaration of a dividend. When he was first induced to join the company he thought that there was in it so much of the element of usefulness, in a great commercial city like London, that it was one of those modern speculations that would speedily turn out successful. His anticipations had not been realised; but looking at the steady increase of the last two years, he felt confident that the time would soon arrive when they should be able to congratulate each other on this undertaking being a successful investment, instead of continuing to be, as hitherto, an unsuccessful one. He had to move that the report and statement of accounts be received and adopted. If any gentleman had any remarks to make or questions to put, he should be glad to hear him.

Mr. GEORGE SHEWARD, vice-chairman, seconded the motion.

Mr. EALES said he for one had always taken a very sanguine view of the prospects of this company, and was glad to find that the chairman entertained views of a similar kind. At the same time, he could not go to the same extent as the chairman, for, looking at the difference between the deficiency this half-year and the half-year ending at the same time in 1863, he found a reduction of about £380. If they deducted from that sum the net receipts in the second half-year of 1863, in order to follow out the estimate of the probable receipts for the coming half-year, there would be found still a considerable deficiency. It was rather a sanguine view to take of the matter to suppose that the receipts would immediately equal their expenditure. He should be glad indeed if that turned out to be the case, but he thought they would have to look a little farther on before they could make profit on the amount they had so long invested; and it seemed to him that the reason they had not been so successful hitherto was attributable to a deficiency of capital. He found that they had but fulfilled one-half of what they undertook to do, and what they hoped still to do. He found that in many cases there was such a delay in the delivery of messages that they could be as speedily delivered by messengers. Such should not be the case. Then again, it was originally intended to have stations all round the metropolitan district, within half-a-mile of each other, which, if carried out, would have a most beneficial effect. But in this they had been thwarted from want of funds. Many complaints had also been made of the inaccuracy of the messages, and some respecting the charges. In every point of view their misfortune—want of capital—had acted and re-acted upon them. And now that the affairs of the company had taken a better aspect, he would suggest that they should endeavour to carry out fully the propositions with which they started; but to do that it was clear that additional capital was required. The shareholders had every confidence in the directors, and he would take the present opportunity of suggesting for their consideration whether additional capital should not be raised. He hoped that at the next half-yearly meeting they should hear something on the subject.

The CHAIRMAN, in reply to Mr. Eales, said he could only say that the original proposition of the company was to have a hundred stations, which they considered would be sufficient for the purpose of encircling the metropolis. The Brighton Company's stations took in messages for this company, and so did the Magnetic, so that if they added those offices to their own they got up the exact number they intended when they started. With regard to delays in the forwarding or delivery of the messages, no one regretted that more than the directors and the manager. They did all they possibly could to prevent it, but frequently the material did not answer the desired purpose. They fined their clerks and messengers for delays, in order to maintain efficiency in their staff, and sometimes the directors would probably be considered harsh for their proceedings in this respect. Any suggestions made by shareholders were most acceptable, both to the directors and the manager. He trusted that before long this company would be paying not the fabulous dividends they sometimes heard of, but such dividends as would justify the early investments in this company as a safe undertaking. Nothing would be wanting on the part of the directors to promote the welfare of the shareholders and to further the success of the company.

Mr. EALES moved a vote of thanks to the chairman, who had always taken great interest in the affairs of the company.

The motion was seconded and carried amidst applause.

The CHAIRMAN, in acknowledging the compliment, said he had declined opportunities of becoming a director in other companies, and had associated himself with the District Telegraph Company, because he thought it was a very useful undertaking, and one which was eminently calculated to promote the vast commerce of this great metropolis.

The meeting then separated.

TELEGRAPHIC EXTENSION IN NEW SOUTH WALES.—We quote the following from the *Age* of the 14th of May:—"Mr. Cracknell, the chief superintendent, is on a visit to Victoria for the purpose of consulting with the head of the South Australian department, Mr. Todd, relative to the construction of an independent line of telegraph between South Australia and New South Wales. At present all messages between these colonies have to pass through the head station of the Victorian department—an inconvenience which has long been a subject of complaint as well as the cause of unnecessary delay."

CORRESPONDENCE.

INDIA-RUBBER COVERED CABLES.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—Absence from London on a cable-laying expedition prevented my seeing a letter in your impression of the 16th ultimo, from Messrs. Hall and Wells, respecting the twenty miles of India-rubber covered core that was sent to me to be manufactured into a submarine cable for the Indian Government, and which I afterwards sent out to Bombay, according to instructions received.

Now I cannot say what treatment the cable met with after its arrival out, whether it was exposed to the sun or not, but Messrs. Hall and Wells are perfectly aware of the fact that no "hot tar" ever came in contact with their core at all. They know very well, as they had every opportunity of seeing, that the yarn is never used in my serving machines until hours after it is saturated with tar, and that it is wound on bobbins, which must necessarily give it time to get quite cold. They expressed themselves perfectly satisfied with the way in which I did the work for them, and if they knew that tar was injurious to caoutchouc, why did the specification compel me to use it? I could as easily have used tanned serving. If the injury was caused by the tar, how is it that the change in the India-rubber commenced on the inside, next the conducting wire? I dare say Messrs. Hall and Wells are very much annoyed at the failure of their core in the Persian Gulf, but it is hardly fair for them to try to get out of a scrape by shifting the blame on my shoulders. If tar caused the mischief (which I am certain it did not), then they have themselves to blame for causing it to be used. But the fact is, India-rubber stands no chance against gutta-percha. I have watched it carefully for years, and I was one of the first who covered wire with India-rubber as long ago as 1846, and if gutta-percha had never been introduced, caoutchouc would no doubt have been used both for submarine cables and land lines, to a limited extent, but gutta-percha is so immeasurably superior in every respect that it is like struggling against fate for the friends of India-rubber to endeavour to compete with it. I picked up a submarine cable last week that had laid more than ten years, and not the slightest change had taken place in the gutta-percha, and I feel certain that it would remain still as unchanged for a hundred or even five hundred years. Can we say as much for India-rubber, when we see it constantly changing? If we bury it in the sea, or in the earth, it becomes converted into treacle; if you stretch it in the air, it shrivels up and peels off the wire.

I have no interest whatever in upholding one more than the other, but I am so thoroughly convinced of the superiority of gutta-percha (having used upwards of 7,000 miles of wire covered with this insulator) that I should never use any other material when the option is given me.

I admit that gutta-percha has failed when extended in the air, and also when placed underground without proper protection, but I have within the last few years laid many miles underground, and also above, which will remain many years without showing signs of decay.

Messrs. Hall and Wells say they guarantee the cables made by themselves only. I do not believe they ever made a single submarine cable, and as regards their powers of production, they required three months to make the twenty miles of core in question, whereas I frequently get sixty miles per week of the Gutta-Percha Company, and I believe they could nearly double this.

I see, from one or two writers in your journal, they have fears that tar will prove destructive to gutta-percha: they may make their minds easy on that score; from tar, gutta-percha has nothing to fear, on the contrary it is one of the best preservatives.

I am very sorry to be obliged to run down India-rubber, but it has had plenty of trials, and, except in a few cases, has signally failed, whereas gutta-percha, if properly treated, never fails, consequently the latter substance must be preferred by those who understand the business they are engaged in, regardless of the strictures and adverse opinions of those who have had no experience and can know nothing whatever of the merits of the question.—Yours obediently,

W. T. HENLEY.

July 28, 1864.

THE ELECTRIC TELEGRAPH COMPANY'S MEETING.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—As we are indebted to your paper for much information on telegraphic matters, it may be interesting to many of your readers to have a brief outline of the meeting held, on the 3rd instant, at the Electric and International Telegraph Company's office. After the usual routine of business, it was made special for granting an additional thousand pounds to the ex-secretary, over and above the thousand pounds already voted to him at the April meeting; which first sum he received, and then applied for more—or the chairman applied for him. From all the information the shareholders could obtain, this gentleman, who had been in the service of the company for fifteen years, and had been receiving for a long series of years £750 per annum, was requested to send in his resignation, to make room, as the directors said, for a more efficient and energetic man. It would appear that some difficulty was in the way of getting the ex-secretary to do this. He did not like the idea of being shelved in favour of one of his own staff, and it was only on the promise of the directors to pension him for life at £300 a-year, that he consented. This having been agreed to, the directors,

in the full swing of their power, brought the proposition forward at the April meeting, and, much to their horror, and the honour of the shareholders, it was rejected. The shareholders at that meeting would have no hand in forming a pension list, but very generously granted him a sum of one thousand pounds, which he accepted; and thus matters were left until the meeting of Wednesday, when the chairman, having fortified himself with a strong party of his friends, and a powerful muster of the telegraph staff (who are enjoined to purchase as much stock as will give them a vote), again returned to the charge, made another demand on the shareholders for the second thousand, and carried it. Now, what I complain of is the power held by directors. In all cases they are enabled, by a rally of their friends, or by the iniquitous system of proxies, to swamp any meeting, whether the case be just or unjust. In this case, we have a gentleman receiving £750 a year, and now, through the caprice, or something worse, of the directors, the shareholders are obliged to support this gentleman in idleness, and pay him at the rate of one pound per day for seven years to come, and this whether there is any dividend or not left for the shareholders—this sum to a gentleman in the prime of life, who may turn to any other pursuit, or may join some opposition company against ourselves. This contrasts very strongly with the report of a banking company in the daily papers, viz., the Union Bank. The case was that of a ledger-clerk, who had been twenty-two years in the service of the bank, and had worked himself up to a yearly salary of £192. This man had retired through failing health, and having applied to his board for some retiring allowance, was offered the sum of £200 in full of all demands, take it or leave it. You will observe this is a case in the opposite extreme, and entirely performed by directors; and yet these men are bankers and merchants, and pay double the amount in dividends that we do, and know the value of money; but still shows the principle how much shareholders are in the power of directors, and who, once elected, there is hardly a possibility of displacing them.

Now, in the place of granting such large sums of money to such men as our ex-secretary, if it had been distributed amongst the hard-working staff who are toiling in the company's service, many of them only receiving sixteen shillings a-week, and on that scanty allowance obliged to keep themselves respectable, and even placed in situations of trust, I say had this sum, voted by the directors, been distributed amongst this class, it would have shown them to be sensible men, who had the interest of the company at heart. As it is, they show themselves deficient in commercial knowledge, and only prepared to carry out their own whims, and set the proprietary at defiance.

A Shareholder.

TELEGRAPHIC NEWS.

Electric and International Telegraph Company.—The directors of this company propose to pay a dividend of 4 per cent., for the half-year ending the 30th of June, on the 15th instant.

Telegraph Clerks' Provident Fund.—A soiree and conversazione is to take place for the benefit of the above fund, on the 8th instant, at Barnsbury Hall, Islington. The members of the International Dramatic Club have kindly volunteered to assist on the occasion.

Telegraphic Progress.—The Liverpool Town Council, at its meeting on Wednesday last, granted permission to the United Kingdom Electric Telegraph and the Universal Private Telegraph companies, to carry their wires above ground, instead of beneath the surface as hitherto.

Telegraphy in France.—We publish, with pleasure, that His Imperial Majesty the Emperor of the French has appointed Professor Hughes, the well-known inventor of the telegraphic instruments which bear his name, to be a "Member du la Conciel du Perfectionment," an appointment similar to the one occupied by the professor on the committee of the Board of Trade, in England, in the years 1859-60-61.

Damage to a Submarine Cable.—Under the above heading a paragraph appeared in this journal on the 26th ult. with respect to the injury sustained from an anchor by the Dover and Ostend cable, the property of the Submarine Telegraph Company. Mr. W. T. Henley requests us to insert the following correction, which we do with much pleasure:—"I undertook to make and lay twenty nautical miles from the Sandetti shoal to Dumpton Gap, near Ramsgate. This cable was to be spliced on to the Dover and Ostend cable as soon as the Magnetic Company had completed the land lines. They have not yet done so, so I have connected the cable to the other and buoyed it. I broke the Dover and Ostend cable in lifting, owing to its decayed condition. I was responsible for it, therefore had to repair it before laying the other."

Printing without Ink.—In the month of January an announcement appeared in the *Typographic Advertiser* of an invention which we thought exceedingly ingenious, and likely to prove of service on telegraph printing instruments: but the meagreness of the information imparted induced us to refrain from any comment thereon. We are now favoured with a few particulars which lead us to hope that a really useful invention has been perfected. "Mr. Hancock, of the Gutta-percha Company has been prosecuting a series of experiments with the view of dispensing with the use of printing ink, and has succeeded in chemically treating the pulp during the manufacture of printing papers, in such a manner that when the paper is impressed upon the uninked types the chemical particles are crushed, and a perfect black impression is the result."

A New Alloy.—A new alloy, described as applicable to the manufacture of all metal articles, bells, hammers, anvils, nails, and non-cutting tools, has been patented by Mons. M. H. Micolon, of Paris. The alloy consists of iron, with manganese or borax. The patentee takes twenty parts of iron turnings or tin waste, eighty parts of steel, four parts of manganese, and four parts of borax; but these proportions may be varied. When it is desired to increase the tenacity of the alloy, two or three parts of wolfram are added. When the cupola is ready, the iron and steel are poured in, and then the manganese and borax; finally, the vessel is filled up with coke; the metal is thus in direct contact with the fuel in the cupola, and by quickly running the fused mass into moulds, bells which possess the sonorousness of silver, whilst the cost is less than bronze, may be obtained.

Historical.—In 1766, 207,600 lbs. of gunpowder, which was stored in the church of St. Nazaire, in Brescia, Italy, was fired by a stroke of lightning, and the explosion reduced about one-sixth of the city to ruins, and killed 3,000 of the inhabitants.

TO CORRESPONDENTS.

Professor Hughes, E. F. G., and Omicron.—Received with thanks. Will appear in our next.

A Constant Reader.—We will reply to your query shortly.

*** Owing to the length of the reports of telegraph companies, a mass of valuable matter has been crowded out this week.

As information respecting Improvements, Extension of Lines, and Progress of New Undertakings will at all times be most acceptable, we hope that our readers will kindly render us assistance, by furnishing us with brief notices of events and occurrences in connection with electrical and scientific progress.

Communications intended for publication must be authenticated by the names and addresses of the writers; not necessarily for insertion.

Letters relating to Advertisements are to be addressed to the Publishers. All other letters and communications to be addressed to the Editor of the *Telegraphic Journal*, 4 & 5, Suffolk-lane, Cannon-street, London, E.C.

The *Telegraphic Journal* can be had of Messrs. Smith & Co., Strand; J. Onwhyn, Catherine-street, Strand; Messrs. Dawson & Co., Cannon-street, E.C.; Messrs. Kent & Co., Paternoster-row, London. Messrs. Heywood & Co., Manchester; at the various railway stations; and of all news-agents, &c., &c.; or it can be supplied, if preferred, direct from the Office on the following terms:—

SUBTERRANEAN TELEGRAPH LINES IN FRANCE.

By Professor Hughes.

France possesses a system for underground telegraphic wires, which has now had the test of several years' practical experience. There are over 2,000 kilometres of wire laid, all in a perfect state of high insulation, which, from the constant and uniform good results obtained, makes the French system worthy to be studied by electrical engineers.

There are seven distinct underground routes for these wires, which lead from the Central Station, in Paris, to the limits of the City, where they are joined (in a small office) to the air-lines leading to the different provinces of France.

In the French system, the iron tubes being solid and hermetically sealed during their entire length, the wires are entirely protected against any mechanical injury. The gases, which are the main cause of the deterioration of the gutta-percha, cannot enter the tube, and even if this infiltration should take place, which has never yet occurred, means are ready to establish a thorough ventilation of the tube. Water, for the same reason, never enters the tube, and, consequently, the insulation of these wires are invariably the same during all seasons of the year.

The following is a short description of these tubes, with the manner of joining them into separate determinate lengths:—Iron tubes, very similar to the ordinary gas tubes, are laid in a trench of 1 yard in depth; they are 2½ yards long, and their diameter is proportionate to the number of wires intended for use. A strong iron wire is introduced into these tubes, whilst being laid, in order to draw in a rope, which serves to introduce the cable. The tubes are then carefully cemented at their junctions with lead, for a distance of 50 yards. At each 50 yards a connecting tube, of a diameter sufficient to slide over the tubes in either direction, serves to join these sections when the entire work is accomplished; this leaves an open space at each 50 yards in order to admit the cable, which, when introduced, the connecting tube is drawn over the ends of the ordinary tubes, and by means of hammered lead carefully closed, thus joining the separate lengths into one entire whole. Larger tubes are employed where there are angles, and at each end of these curved tubes spaces are left for the connecting tube already mentioned. The gutta-percha wires, formed into a cable are introduced at each 200 yards, where they are united to the next section. In drawing these cables into the tube, the iron wire already within the pipe serves to introduce the strong rope, which draws the cable through the tubes. The cable is attached directly to an iron guide, having three iron rollers on its surface, in order to keep the guide in the centre of the tube whilst being drawn by the rope; the rope and cables are drawn through by a windlass, the rope passing over a pulley in the trench directly in the arc of the tubes. This operation is rapidly made with the aid of five men, who can easily lay one mile per day, including the joining up of the different sections, and the lines established in Paris by this system have all been made with great facility.

There are now 52 kilometres of subterranean lines in Paris, 1,450 kilometres of wire enclosed in these tubes. Two distinct routes leave the Central Station, branching to the Railways du Nord, Strasbourg, Vincennes, Lyons, Orleans, Sceau, and Rennes. The tubes vary from 60 to 120 millemetres in diameter, according to the number of the wires intended for use. Tubes of 60 millemetres receive easily 28 wires; 100 millemetres receive 49 wires; and those of 120 millemetres have 77 wires. The copper-conducting wire is formed of a strand of four wires, each having a diameter of half a millemetre. They are covered with two coverings of gutta-percha, giving in total a diameter of five millemetres. These are separately covered with tarred hemp, and formed into cables of seven wires, protected with a thick covering of tarred hemp. Ratties & Co., of Paris, are makers of these wires.

I have lately inspected these cables, which, during four years' use have never had the slightest defect, and I found that the gutta-percha was in a most perfect state of preservation. The tar having in some measure been absorbed, the gutta-percha was slightly coloured with the tar, but its original elasticity was preserved and its electrical conditions were in a more perfect state than when first laid.

The following are the results of the electrical tests, made with a very sensitive galvanometer, and with a Daniell's battery of from 100 to 200 cells.

Length of cable in kilometres.	Number of years in use.	Number of Daniell's cells.	Loss to earth on galvanometer through total length.	Amount of charge on galvanometer through total length.	Amount of discharge on galvanometer through total length.	Resistance of insulation in kilometres for each kilometre.
10	1½	200	1	5	4	1,000,000
10	4	200	0	4	4	4,900,000
6	3	200	½	9	8	2,000,000
6	4	200	⅛	3	3	1,000,000

The cost of laying subterranean wires by this system, at Paris, was as follows:—Iron tube, 120 millemetres diameter, in which are placed sixty-three wires, contained in nine cables of seven wires each. The entire cost of tube, trenches, placing wires, &c., complete, eight francs per yard, or twelve centimetres each wire per yard. The cables, with seven insulated wires, cost 2,900 francs per kilometre. This would make 414 francs each wire per kilometre, and, adding the cost of the iron tube, with laying, &c., the total price would be 534 francs per kilometre, and as these tubes are, after four years' use, in a most perfect state of preservation, it is but reasonable to suppose that they will be serviceable for many years to come.

Thus it will be seen that the French system, whilst giving superior electrical results, possesses, from its entire freedom of derangement, and from its duration, a great economy over all other telegraphs. This system is now being introduced throughout the provinces in France. Lyons has 192 kilometres; Bordeaux, 100; Rouen, 84; and at present it is being established throughout the city of Marseilles.

THE MEETINGS OF TELEGRAPH COMPANIES.

The annual and half-yearly reports of several telegraph companies have been presented to shareholders, and the proceedings at the various meetings of proprietors have been duly published in these columns. It will be unnecessary, therefore, on the present occasion to go into an analysis of the reports, or to criticise the doings at the meetings; but there are several matters in connection with these periodical renderings to which we shall advert. The directors of the Electric and International Telegraph Company met their shareholders with a very favourable statement, and the routine business of declaring a

dividend at the rate of 8 per cent. per annum was very quickly despatched. At the conclusion of the general, a special meeting was held for the purpose of considering the case of Mr. Fourdrinier, which gave rise to a deal of discussion on the occasion of the last meeting. With respect to the principle in dispute between the directors and the shareholders, we must coincide with the general view of the question taken by Mr. Glass, that the proprietors must leave the internal economy of a company in the hands of the directors; unless, through mismanagement, the affairs of the undertaking are discovered to be in jeopardy. This was not the condition of things in the instance under consideration, and we must, therefore, regret the captious spirit in which some of the shareholders received the proposition of the directors to award an additional £1,000 to Mr. Fourdrinier, in acknowledgment of long and faithful service. Notwithstanding a little opposition the meetings passed off very satisfactorily, and the old company is certainly in a very flourishing condition. The directors of the Mediterranean Extension Telegraph Company have also reported progress, and have declared a good dividend, besides appropriating a large sum to the reserve fund. The United Kingdom Electric Telegraph Company held its meeting on the 30th ultimo. Paradoxical as it may appear, when there is nothing to say it is a maxim with directors to make a voluminous statement. Accordingly we find the chairman's introductory address, on this occasion, teeming with encouragement, and his advice to shareholders was "hope on, hope ever." Proprietors get tired of the old story concerning "the present position and future prospects of the company," and sit impatiently whilst suppositionary statistics are glibly uttered. They know that "*if* they allowed the same increased proportion of messages to take place for the additional mileage about to be brought into operation, and *if* the number of messages increased in a similar ratio, the result would be" so-and-so; and *if* this, that, and t'other were put together and multiplied, the total would be equal to the dividend paid. It is very vexatious for directors to come before the proprietors once a-year with a long and uninteresting story of the magnitude of their operations and the increase of their traffic, with voluminous figures to show the grandeur of their enterprise—and figures will prove anything; but what does all this avail? It does not pay. It is unwelcome information to shareholders to hear that after leaving their capital unremunerative for four years they are still to wait for dividends; and when it transpires that the directors are entitled by an unseen and unread deed of settlement to £1,000 per annum for their services, and that some of the chief officers of the unprofitable concern are receiving princely salaries, it is not surprising that shareholders become dissatisfied, and that complaints are general. While this kind of management is tolerated, no great good can be predicated of the undertaking. The principle of a uniform cheap rate for messages is commendable, and is appreciated by the public; but until some new life is infused into the directorate, and until the exorbitant salaries of the chief officers of this company, as already observed, are brought within reasonable limits, the shareholders will stand but a remote chance of receiving a return for the capital invested. The London District Telegraph Company held its half-yearly meeting on the 4th instant. The report showed that a considerable reduction had been effected in the annual loss on the capital account, and a hope was expressed that the income next year would cover the expenditure, and enable the directors to recommend the declaration of a dividend. The affairs of this Company are managed with a scrupulous regard to economy, which will surely bring its own reward. The sphere of the London District Telegraph Company is limited, but when the public of the great metropolis learn to use the telegraph more generally, the property of this Company will prove to be the most profitable of all the telegraphic enterprises.

TELEGRAPHS IN THE FEDERAL ARMY.

We are indebted to the *American Artizan* for the following particulars of the telegraph in the camp, extracted from the Report of the Secretary of War:—

"The service of the field telegraph trains, in the hands of the corps, and making part of its equipment, has been conducted with a fair and, in some instances, a marked success of the different military departments. The liberality of the war department has allowed a development of this branch of the duty greater than was recommended at the date of my last report, and with results which have justified the action. It remains, in my view, only to follow the path of development indicated by the experience of the past year to secure for our armies a service of field telegraphs, with portable lines, so superior as to render our advance in improvements of this character as notable as those which have marked the progress of our armies in other branches of military appliances.

"In my last annual report there was brought to the attention of the department the improvement in telegraphic apparatus which the ingenuity of American artisans, stimulated by the field opened to them by this war, and the call for improved equipments for the trains for the signal corps of the army, had inaugurated. The practical experience of the past year, indicating the wants of the service, and the same ingenuity constantly exercised to overcome these wants and to perfect the material, have led to developments in the art which are now attracting the attention of electricians, and which, if they fulfil the promise of their seeming, will go far to revolutionize the appliances for the transmission of signals by electricity. It is already a subject of consideration whether the appliances and the modes for generating a magneto-electric current, as first used for telegraphy in this country, in the experimental instruments made for the signal corps to dispense with the clumsy and untransportable voltaic battery, are not these appliances and that mode which will be necessary to transmit signals through submarine cables of uncommon length, as that proposed to cross the Atlantic. This is, of course, theoretical only.

"The use of the instruments in the army has led incidentally to their examination for the naval force of the United States. Their use for civil purposes attracts attention. The ingenuity of the inventor, Mr. G. W. Beardslee, of New York,—turned to the subject of increasing the powers of the instruments to enable them to work at greater distances, and to apply the magneto-electric current in the same manner as generated by the field machinery, under circumstances when, with the first devised instruments, it was difficult or impossible,—has produced, with a construction novel in this country and in Europe, a signal-sounder, by which the signals transmitted are addressed to the ear; messages transmitted by this instrument may be read as with instruments of common usage.

"Experiments have been ordered with this apparatus. If, as is the opinion of the inventor, it can be used at any great distance, and with the compact and perfectly transportable apparatus of the magnetic instruments of field trains, it promises a development of field telegraphy before impossible, and will favourably influence the telegraphic enterprises of the country. Should the experiments ordered warrant the course, the signal trains of the army will be equipped with both the dial instruments already in use and the instruments now mentioned. There are opportunities for the employment of both. It is with some gratification that the attention of the Secretary of War is invited to these results. The credit of whatever success shall hereafter attach, in civil or military use, to American apparatus, based on these principles and on this style of its applications, will be largely due to that wise view of the war department which first gave it opportunity for development.

"During the year there have been in the service of the corps thirty field trains, distributed as follows:—

In the Army of the Potomac	5
In the Department of the Cumberland	5
In the Department of the Gulf	3
In the Department of North Carolina and Virginia	3
In the Department of the South	2
In the Department of the Tennesse	6
In the Department of Ohio	2
At the Signal Camp of Instruction, Georgetown, D.C.	3
At the U. S. Military Academy, West Point, N. Y.	1
Total	30

"Seventeen have been distributed since May 1, 1863. Of these

trains, some have been equipped with five and others with ten miles of insulated wire. There are carried in the trains lances for setting up the wire, when that is necessary; reels, portable by hand, carrying wire made purposely flexible for this particular use, and various minor appliances which experience has proven useful. A military organization is directed for each train.

"In duty of this kind, the style of construction of the trains, the equipment they are to carry, and the military organization to be provided for their use, to enable them to be most rapidly and anywhere brought into action, are the subjects for study. The particular instrument to be equipped is of secondary consideration. The soldiers drilled to the duty of construction acquire in a short time a remarkable skill in the rapid extension of these lines. As was anticipated, they have proved valuable auxiliaries to the services of the corps, and have sometimes rendered them available when they would, without, have been impossible. The greatest reported distance at which the instruments have worked is twenty miles. The average distances at which they are used are from five to eight miles. The average speed of the most rapid construction is reported to be at the rate of a slow walk.

"At the first battle of Fredericksburg, field trains were first in the history of the war used on the battle-field under the fire of the enemy's batteries. The movements to be made on the day of that battle were of the first magnitude. The movements of the retreat were perilous to the whole army. The trains in use contributed something to the success of those movements."

ABRIDGMENTS OF SPECIFICATIONS RELATING TO ELECTRICITY AND MAGNETISM, THEIR GENERATION AND APPLICATION.

II.

In order to render the abridgments of specifications, in which electricity and magnetism are referred to, as complete as possible, the following brief summary of the progress of knowledge in reference to those imponderable forces and their applications, up to the time of the commencement of the patents, is prefixed. The summary also embraces any discoveries, inventions, or applications that are not treated of in the body of the work, at whatever date they may have been invented or brought into use.

This summary is divided into two heads:—1. Magnetism; 2. Electricity.

MAGNETISM.

This branch of the subject demands priority, being the most ancient form under which the action of the above-named imponderable forces was known. Under this head is included that species of force which is most developed in ferruginous matter, by which one particle attracts or repels another particle at appreciable distances; also applications of the phenomena consequent on these attractions or repulsions to useful purposes; also the nearly-allied force of diamagnetism.

The earth itself and the natural magnet or loadstone (called by some "lodestone") are the earliest examples of the magnetic power, although for countless ages such a power was unknown to man; and when the force was known, its simple and general properties were only observed in what may be termed the natural objects in which its manifestation was most apparent. The force itself was, during those comparatively dark ages, treated rather as a property of the loadstone itself (in relation to the earth and to iron), than as a distinct force, which could be transferred, and which more or less affects every substance on our globe, and most likely in the material universe. In tracing the slightest sketch of its history, therefore, it will be found that in early times the magnetic power was believed to belong only to the loadstone; it was next believed to belong only to the loadstone, and iron or steel; now, however, every material substance is found to be affected more or less by its influence. The imponderable forces of light, heat, and chemical action have also their action upon the magnetic force, and are acted upon by it. Even life itself (the vital force, *vis vivæ*) is believed by some to possess intimate relations to the magnetic power.

B.C. 2600-1040.—The Chinese discovered the attractive power of the loadstone. In reference to the loadstone's directive power, there is mention made of the employment of a needle "to determine the four parts of the world" on a "carr," in Duhalde's *General History of China*, when the Emperor Hoangti gave battle to Tchi Yeou (about 2600 B.C., according to Davis's *Chinese*, p. 83); "by this method he overtook Tchi Yeou, made him prisoner, and put him to death." In another part of the same book it is mentioned that Tchieou Kong gave certain ambassadors an instrument to direct them on their way home; one side of this instrument pointed towards the north, the other towards the south; this happened about 1040 B.C. Great doubts are, however, entertained of the veracity of the Chinese early history: therefore, of these epochs also. (See *Encyclopædia Metropolitana*, Vol. III., art. Magnetism, p. 736; also *Abridgments of the Specifications relating to Marine Propulsion*, Part I., p. 4; also Sir W. Snow Harris' *Rudimentary Magnetism*, Parts I. and II., pp. 1, 3, and 5; also Davis's *Chinese*, pp. 277, 278.)

B.C. 1000.—Magnes, a shepherd, is said to have been detained on Mount Ida, in Phrygia, by the nails in his boots or by his crook; the word "magnet" is thus supposed to be derived from the name "Magnes." Some authors derive the word "magnet" from the province of "Magnesia," in Lydia, whence the Greeks are said to have obtained the loadstone about 1000 years before Christ. (See *Encyclopædia Metropolitana*, Vol. III., art. Magnetism, p. 735; also Sir W. Snow Harris's *Rudimentary Magnetism*, Parts I. and II., p. 1.)

B.C. 1000-600-500-400-100.—Homer (1000 B.C.); Thales, Pythagoras (600 B.C.); Euripides, Plato (500 B.C.); Aristotle (400 B.C.); the Roman poet Lucretius (in his philosophical poem, "De Rerum Natura"), an Cicero (100 B.C.), mention the attractive powers of the loadstone. (See *Encyclopædia Metropolitana*, Vol. III., art. Magnetism, p. 735; also Sir W. Snow Harris's *Rudimentary Magnetism*, Parts I. and II., pp. 1, 2, and 3.)

A.D. 100.—Pliny, in the 36th book of his Natural History (written in the first century after the Christian era), has an obscure allusion to the repulsive power of the loadstone. (See Sir W. Snow Harris' *Rudimentary Magnetism*, Parts I. and II., p. 8.)

A.D. 400.—Marcellus, who flourished about A.D. 400, "alludes to the magnet as the attractor and repulsor of iron." (See Sir W. Snow Harris' *Rudimentary Magnetism*, Parts I. and II., p. 8.)

A.D. 500.—The Chinese had craft "sailing on the Indian Ocean under the supposed guidance of south magnetic indication at least 700 years before it was employed by European nations," according to Humboldt's researches. (See Sir W. Snow Harris' *Rudimentary Magnetism*, Part III., p. 135.)

A.D. 500.—Aëtius about the year 500, mentions that "those who are troubled with the gout in their hands or their feet, or with convulsions, find relief when they hold a magnet in their hand." (See *Aëtii Op.* l. ii. c. 25; also Beckmann's *History of Inventions*, Bohn's edition of 1846, Vol. I., pp. 43, 44.)

A.D. 1111.—The Chinese appear to have been long aware of the variation of the compass. In a Chinese work on medicine and natural history about 1111 the following passage occurs:—"When a steel point is rubbed with the magnet it acquires the property of pointing to the *south;* yet it declines always to the east, and is not due south. If the needle be passed through a wick (made of a rush) and placed on water, it will also indicate the south, but with a continual inclination towards the point *ping*, or five-sixths south;" this was the variation at Pekin. (See Davis's *Chinese*, pp. 277, 278; also Sir W. Snow Harris' *Rudimentary Magnetism*, Part III., p. 80.)

A.D. 1200.—Guiot de Province mentions, in a poem written by himself, that mariners used a "touched" needle, fixed on a bit of straw, prior to the year 1200, for a mariner's compass. (See *Encyclopædia Metropolitana*, Vol. III., art. Magnetism, p. 736.)

A.D. 1242.—The captains navigating the Syrian Seas, in 1242, mounted a common sewing-needle on a piece of reed or cork, and allowed it to float on the surface of water, the sewing-needle having been rendered magnetic. This arrangement was used as a compass-needle. (See Klaproth, *Lettre à M. Humboldt*, p. 57; also Sir W. Snow Harris' *Rudimentary Magnetism*, Part III., pp. 135, 136.)

A.D. 1260.—Paulus Venetus, in 1260, brought the compass from China to Italy, according to Dr. Gilbert. (See *Encyclopædia Britannica*, 8th edition, art. Magnetism, p. 2.)

A.D. 1269.—Peter Adsiger, in a Latin letter (dated 1269) in the University of Leyden, sets forth an azimuth compass having a needle mounted on an axis, and mentions the declination of the magnetic needle. (See *Encyclopædia Metropolitana*, Vol. III., art. Magnetism, p. 737.)

A.D. 1320.—Flavio de Giova, of Amalfi, is said by the Italian writers to have invented the mariners' compass about the year 1320. (See *Encyclopædia Metropolitana*, Vol. III., art. Magnetism, p. 735.)

A.D. 1492.—Columbus remarked the variation of the compass in 1492. (See *Encyclopædia Britannica*, 8th edition, art, Magnetism, p. 2.)

A.D. 1576.—Robert Norman, a mathematical instrument maker in or near London, discovered the dip of the magnetic needle in 1576. and found it then in this latitude to be 71° 50', or thereabouts. (See De la Rive's *Treatise on Electricity*, Vol. I., p. 165; also *Encyclopædia Metropolitana*, Vol. III., art. Magnetism, p. 738; also Mary Somerville's *Connection of the Physical Sciences*, p. 335.)

A.D. 1590.—Julius Cæsar, a surgeon of Rimini, observed the conversion of iron into a magnet, by position alone, in 1590. (See *Encyclopædia Britannica*, 8th edition, art. Magnetism, pp. 2, 3.)

A.D. 1600.—Gilbert, in his work "De Magnete," published in 1600, "represents a blacksmith hammering a steel bar in the position of the inclined needle." (See Sir W. Snow Harris' *Rudimentary Magnetism*, Parts I. and II., pp. 93, 94; also *Library of Useful Knowledge*, Magnetism, p. 25; also *Encyclopædia Metropolitana*, Vol. III., art. Magnetism, p. 739.)

A.D. 1622.—Professor Gunter, of Gresham College, discovered the change of declination in the same place in 1622. (See De la Rive's *Treatise on Electricity*, Vol. I., p. 165.)

A.D. 1630.—Gassendi, about 1630, observed that an iron bar was magnetic which had been in one position for a lengthened period of time, and had been struck by lightning. (See *Encyclopædia, Britannica*, 8th edition, art. Magnetism, p. 3.)

A.D. 1650.—Bond, about 1650, discovered the true progress of the deviation of the compass. (See *Encyclopædia Britannica*, 8th edition, art. Magnetism, p. 3.)

A.D. 1683.—Dr. Edmund Halley, in 1683, published his theory of terrestrial magnetism. (See *Encyclopædia Metropolitana*, Vol. III., art. Magnetism, p. 739.)

A.D. 1684.—Hooke, in 1684, heated iron rods in the magnetic meridian, and allowed them to cool in the same position, thus imparting magnetism to them. (See *Encyclopædia Britannica*, 8th edition, art. Magnetism, p. 3.)

A.D. 1687.—Newton, in his *Principia* (published in 1687) notices the neutralizing effect of the interposition of an iron plate between a magnet and a body acted upon by it. (See Newton's *Principia*, 2nd Book, 23rd Prop., Sec. 5; also Sir W. Snow Harris' *Rudimentary Magnetism*, Part. III., pp. 11, 12.)

A.D. 1700.—Morgagni, about the beginning of the 18th century, used the magnet "to remove particles of iron which had accidentally fallen into the eyes." (See Beckmann's *History of Inventions*, Vol. I., p. 44; also Maunder's *Biographical Treasury*.)

A.D. 1722.—Mr. Grayham, an instrument-maker in London, discovered the diurnal variation of the magnetic needle in the year 1722. (See *Encyclopædia Metropolitana*, Vol. III., art. Magnetism, p. 739; also Sir W. Snow Harris' *Rudimentary Magnetism*, Part III., p. 86.)

A.D. 1722.—Marcel, in 1722, "observed that a bar of iron acquired a temporary magnetic state by position alone." (See Sir W. Snow Harris' *Rudimentary Magnetism*, Parts I. and II., pp. 91, 92.)

A.D. 1730.—Savery, in 1730, magnetized hard steel bars by fitting one bar with armatures, and stroking the other bars with it, the bars being in the magnetic meridian. (See Sir W. Snow Harris' *Rudimentary Magnetism*, Parts I. and II., pp. 92, 93.)

A.D. 1734.—Swedenborg, in 1734, wrote upon magnetic phenomena. In his remarkable treatise, the "Principia," the spiral, helical, or vortical character of the motion of the force producing magnetic effects is prominently set forth and figured in drawings; various particulars respecting the declination of the magnetic needle are also stated; and many laws of the magnetic force theoretically indicated, that have since been proved by practical experiment. Experiments and illustrations abound in this work. (See *Principia Rerum Naturalium, sive Novorum Tentaninum Phænomena Mundi, elementaris philosophice explicandi*, Fol. Dresden, 1734, more particularly pp. 123-380, in Vol. I. of "Swedenborgii Opera.")

A.D. 1746-1747.—Dr. Gowan Knight, F.R.S., a London physician, in the year 1746-1747, proposed a method of magnetizing steel bars by gradually withdrawing the opposite poles of magnets from beneath them, the poles being in contact with the steel bars. (See Sir W. Snow Harris' *Rudimentary Magnetism*, Parts I. and II., pp. 84, 85.)

A.D. 1749.—Du Hamel, about the year 1749, made a further application of Dr. Knight's method of magnetizing. Two bars were magnetized at one time by being made the opposite sides of a rectangle, the other sides being formed by soft iron bars. (See Sir W. Snow Harris' *Rudimentary Magnetism*, Parts I. and II., pp. 85, 86.)

A.D. 1750.—Professor Wargentin, secretary to the Swedish Academy of Sciences, in 1750, noticed the effect produced on a magnetic needle by the northern lights. (See *Encyclopædia Metropolitana*, Vol. III., art. Magnetism, p. 740.)

A.D. 1750.—Michell advanced the idea (in his treatise on Artificial Magnets, published in 1750) that in all the experiments of Hawksbee (1712), Dr. Brook Taylor (1721), Whiston, and Muschenbroek (1724), "the force really may be in the inverse duplicate ratio of the distances, proper allowance being made for the disturbing changes in the magnetic forces so inseparable from the nature of the experiment." (See Sir W. Snow Harris' *Rudimentary Magnetism*, Part III., p. 20.)

A.D. 1750.—Michell, in 1750, employed a method of magnetizing, which he designated as "the double touch." Several steel bars to be magnetised are placed in one straight line on a horizontal plane, and the opposite poles of two powerful magnets, or of a compound magnet, are moved backwards and forwards vertically over the series, beginning and leaving off at the centre. (See Sir W. Snow Harris' *Rudimentary Magnetism*, Parts I. and II., pp. 86, 87.)

A.D. 1751.—Mr. John Canton, an English philosopher, in 1751, combined the magnetizing processes of Du Hamel and Michell. (See *Library of Useful Knowledge*, Magnetism, p. 47; also Sir W. Snow Harris' *Rudimentary Magnetism*, Parts I. and II., p. 87.)

A.D. 1756.—Mr. Canton, about 1756 found (from 4,000 observations) that the daily variation of the needle was greater in the summer than in the winter months. (See *Encyclopædia Metropolitana*, Vol. III., art. Magnetism, p. 739.)

A.D. 1757.—Euler, Bernouilli, and Descartes, about 1757, in terrestrial magnetism, advanced the theory that the magnetic fluid moved from the equator to the poles. (See *Encyclopædia Britannica*, 8th edition, art. Magnetism, pp. 4, 5.)

A.D. 1759.—Æpinus' celebrated treatise, "Tentamen theoriæ Electricitatis et Magnetismi," was published in 1759; this treatise contained a method of making magnets, and a theory of magnetism. The method of making magnets was a combination of Du Hamel's with Michell's "double touch;" magnets were used in place of the cross bars of soft iron. The theory was very like Franklin's single-fluid electric theory, but without the transference therein supposed. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, p. 54; also *Library of Useful Knowledge*, Magnetism, pp. 33-36 and 47, 48; also Sir W. Snow Harris' *Rudimentary Magnetism*, Parts I. and II., pp. 87, 88, and Part III., pp. 130, 131.)

A.D. 1760.—Mayer read a paper (not since published) before the Royal Society of Gottingen, in 1760. In this paper Mayer finds the force of magnetic attraction to correspond with the general law of that of gravitative attraction, viz., that it is according to the inverse duplicate ratio of the distances. (See Sir W. Snow Harris' *Rudimentary Magnetism*, Part III., p. 20.)

A.D. 1770.—Father Hehl, about 1770, communicated his discoveries relating to the effect of certain magnetized steel plates in the cure of diseases, to Anton Mesmer. (See Beckmann's *History of Inventions*, Vol. I., p. 46.)

A.D. 1772-1773-1774.—Mr. Wales noticed the effect of local attraction upon mariners' compasses. This gentleman was the astronomer to Captain Cook during his voyages in 1772, 1773, and 1774, and made the above-mentioned observations during that period. (See *Encyclopædia Metropolitana*, Vol. III., art. Magnetism, p. 745; also Sir W. Snow Harris' *Rudimentary Magnetism*, Part. III., p. 161.)

A.D. 1775.—Graham, in 1775, suggested the determination of the magnetic intensity in different parts of the globe by means of the needle of oscillation or magnetic pendulum. (See Sir W. Snow Harris' *Rudimentary Magnetism*, Part III., p. 93.)

A.D. 1776.—M. Lambert published two beautiful memoirs on the laws of magnetic action in the 22nd volume of "Histoire de l'Académie Royale des Sciences," Berlin 1760. In the first of these investigations, the action of a bar magnet upon a magnetic needle is set forth, the bar magnet being placed so that its axis is always pointed to the centre of motion of the needle, and at such a distance from the needle as to deflect it a given angle from the meridian; from the curve thus obtained the laws of magnetic action are assigned in reference to the needle's centre of motion. By this arrangement an equilibrium is obtained between three forces, viz., the magnetic force of the needle, the directive force, and the force of the magnet by which the needle is deflected or drawn from its meridian. The results obtained by this investigation are as follows:—First, "that the action of magnetism on a a magnetic needle, considered as a lever, is proportionate to the sine of the angle of obliquity of its direction; and that hence the effective force which operates in restoring the needle to its meri-

dian, when drawn aside from it, is directly as the sine of the angle of its deflection." Second, that the magnetic force varies in the inverse duplicate ratio of the distances, attended with the singular result that the common centre of attraction is outside of the needle; this fact approximates the analogy of magnetic force to that of gravitation in a remarkable degree. In the subsequent memoir the "curves of the magnetic current" are investigated by the "action of the directive or polar force of a "magnet upon a small needle;" the general laws of magnetism, and the position, size, figure, and force of the great magnet, which M. Lambert supposes to reside in the earth, are also examined. (See Sir W. Snow Harris' *Rudimentary Magnetism*, Part III., pp. 20-23.)

A.D. 1778.—Brugmans, in 1778, observed and recorded the repulsion of bismuth and antimony by the magnetic poles, thus laying the foundation of the science of diamagnetism. (See Sir W. Snow Harris' *Rudimentary Magnetism*, Parts I. and II., p. 76.)

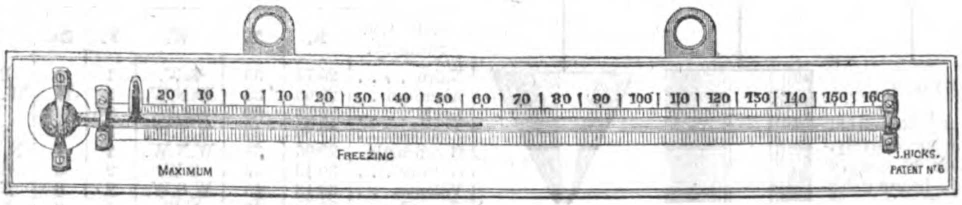
A.D. 1779.—Mr. Benjamin Wilson (in the Philosophical Transactions for 1779) published Dr. Gowan Knight's method of forming artificial magnetic paste, by means of comminuted iron and linseed oil. (See De la Rive's *Treatise on Electricity*, Vol I., pp. 203, 204; also *Encyclopædia Metropolitana*, Vol. III., art. Magnetism, p. 752.)

A.D. 1779.—Dr. Ingenhouz, in 1779, proposed a mariners' compass consisting of a magnetic needle enclosed in water or some other suitable fluid, in order to steady the needle. (See Sir W. Snow Harris' *Rudimentary Magnetism*, Part III., pp. 144, 145.)

A.D. 1780.—Coulomb, about 1780, propounded his double-fluid theory of magnetism; he also proposed a method of magnetizing by the "double touch," the bar to be magnetized being placed between two powerful magnetic poles. (See Sir W. Snow Harris' *Rudimentary Magnetism*, Part III., p. 131, and Parts I. and II., p 88)

A.D. 1786.—Cavallo, in 1786, made many experiments, proving that brass acquires magnetic power by hammering. (See *Library of Useful Knowledge*, Magnetism, p. 90.)

SMITH, BECK, & BECK'S NEW MAXIMUM THERMOMETER.



IT has long been a subject of complaint on the part of those engaged in electrical investigations, that there existed no reliable and exact maximum thermometers. We have had an opportunity of examining a most ingenious and efficient instrument, which has recently been introduced by the well-known and eminent philosophical instrument makers, Messrs. Smith, Beck, & Beck, of Cornhill.

The great superiority of this instrument over all other maximum thermometers which have come under our observation consists in its extreme simplicity, and the impossibility of putting it out of working order.

There is in it no contraction of the tube, no particle of air, nor any metallic or other index for registering the maximum point, all of which plans are open to objection.

It differs in construction from an ordinary mercurial thermometer in having a supplementary chamber near the bulb-end, filled with mercury, as shown in the woodcut above.

When in use, this thermometer should be placed horizontally, and after each observation should be turned with the bulb downwards, until the mercury fills the supplementary chamber: the mercury in the bore then indicates the exact temperature at the time, and the instrument is set. As the heat increases, the mercury expands in the ordinary manner; but on a decrease of temperature, instead of the column in the tube receding, the bulb feeds itself from the supplementary chamber, the end of the column exactly indicating the maximum point.

MEDITERRANEAN EXTENSION TELEGRAPH COMPANY.

THE ordinary half-yearly meeting of this company was holden on Friday, the 5th instant, at the London Tavern, Bishopsgate-street.

There was a fair attendance of shareholders, and the following directors were present:—Sir James Carmichael, Bart., deputy chairman of the company; G. B. Carr, Esq.; Samuel Gurney, Esq., M.P.; and Alexander Devaux, Esq.

The chair was occupied by Sir JAMES CARMICHAEL, Bart.

The CHAIRMAN, in opening the proceedings, called upon the secretary to read the advertisement by which the meeting was convened.

This having been done by the secretary, and the report and statement of accounts having been taken as read,

The CHAIRMAN said he was sorry to have to apologise for the absence of their worthy chairman, who was prevented from attending the meeting from an attack of erysipelas, but he hoped that that was not of a very serious character. The half-yearly report was very short, and he trusted that they would think it was a satisfactory one. He did not think it was necessary for him to offer many remarks upon the report, but there was one point which required explanation. There was a slight decrease in the revenue, which was entirely owing to the interruption that occurred on the Malta and Alexandria line; but that line had now been thoroughly repaired and restored. The revenue now averaged more than £300 a week, which was upwards of a third more than that of last year. He thought that that would be considered very encouraging. Messages from Malta, which used to occupy one, two, and three days, now come in six or seven hours, which seemed to him to be a very satisfactory matter. And he trusted that, by the Italian Government effecting improved insulation, and carrying out other improvements at the different stations, they should be able to transmit messages in a much shorter time than at present between Malta and London. He should have to ask the shareholders for power to the directors to borrow from their bankers such a sum of money as would enable them to pay the dividend. He hoped that the present would be the last time when it would be requisite to ask the shareholders to grant the directors such powers, as the Italian Government had promised now to settle with them quarterly. He moved that the report and statement of accounts be received and adopted.

Mr. CARR seconded the motion.

Mr. F. W. FLOYD said, as a shareholder, who objected to the borrowing of money to pay a dividend, he wished to know if the directors had any idea when the next payment would be made by the Italian Government.

The CHAIRMAN.—We expect the payment daily; certainly it will be paid in a week or ten days. We may not have to borrow money at all to pay dividend, but the directors thought it desirable to ask power from the meeting to borrow money in case it should be requisite. He thought that the money due to them would be remitted in eight or ten days.

Mr. FLOYD.—Then it is only in case of necessity that you ask for borrowing powers?

The CHAIRMAN.—It is only in case of necessity.

Mr. FLOYD.—I would rather wait.

The CHAIRMAN.—But there is a certain stock of preference shares that must have the interest paid, and we thought it better that the whole of the stock should be paid at once.

Mr. FLOYD.—It is the appearance of borrowing money to pay a dividend.

The CHAIRMAN.—Yes, but then that is because we are waiting until a remittance is sent from Turin.

Mr. FLOYD.—Yes, but there is the interest; and besides, there is the very bad appearance of borrowing to pay dividend in the market.

The CHAIRMAN hoped that the present would be the last time when they should have any occasion to refer to a proposal to borrow money in order to enable them to pay a dividend.

THE CHAIRMAN then put the motion that the report and statement of accounts be received and adopted. The motion was unanimously agreed to.

The CHAIRMAN moved, that the directors be authorised to borrow from the company's bankers such a sum of money as would be necessary to mak up, with the balance in hand, a sufficient sum for the payment of divide

Mr. CARR seconded the motion, which was unanimously agreed to. n

The CHAIRMAN moved, that Mr. Samuel Gurney, M.P., and C Hamilton, the retiring directors, be re-elected directors of the company.

Mr. McDOUGALL seconded the motion, which was carried unani tors for

A SHAREHOLDER moved a vote of thanks to the board of d seconded their attention to the interests of the company. The motion v and carried unanimously.

The CHAIRMAN returned thanks, after which the meeting ke up.

ARRANGEMENTS FOR METEOROLOGIC TELEGRAPHY.

(Continued from page 56.)

In continuation of this treatise of Admiral FitzRoy's, we have illustrated with engravings the various cautionary or storm-warning signals employed. Fig. 1 represents the North Cone (referred to in No. 31, p. 56), which, inverted, represents the South Cone. Fig. 2 is the Drum, which indicates

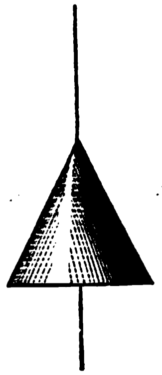


Fig. 1.

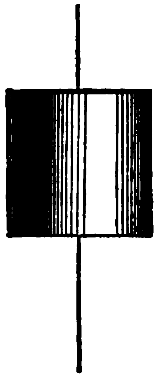

Fig. 2.

that storms may be expected from more than one quarter successively. Figs. 3 and 4 are used to convey intelligence of probable heavy gales (Fig. 3 from the northward, and Fig. 4, which is the same signal inverted, from the southward). The table following will enable the reader, after a little consideration, to fully comprehend the weather bulletins published in the journals of the day by the Meteorologic-office of the Board of Trade. The subsequent information will show the stations in connection with each telegraph company receiving cautionary signals.

PROBABLE.

Wednesday. On Northern Coasts. *Thursday.*

N.W. to N.E. and back, strong, squally, showery.	N. to W., strong, squally to moderate.

Western.

As above.	As above.

Southern.

W.N.W. to N.N.E., strong, squally. Rain or hail at times.	N.N.E. to W.N.W., strong to fresh.

Eastern.

N.W. to N.E. and back, gales to fresh. Some rain or snow.	As next above.

Northern = Scotland. Western = Ireland, Wales, and adjacencies.
Southern = English Channel and Biscay Bay.
Eastern = Eastward England and North Sea.

Cautionary signals on Monday.

Explanation.

B.—Barometer corrected and reduced to 32° at half tide level. Each ten feet of vertical elevation causing about one hundredth of an inch diminution; and each 10° above 32° causing nearly three hundredths increase. T.—Thermometer exposed in shade. W.—Wind, direction of (true—two points left of magnetic). F.—Force (1 to 12—estimated). Ex.—Extreme force since last report. D.—Direction of extreme force. I.—Initials; b.—blue sky; c.—clouds (detached); f.—fog; h.—hail; l.—lightning; m.—misty (hazy); o.—overcast (dull); r.—rain; s.—snow; t.—thunder. R.—Rain-fall, snow, or hail (melted), since last report. S.—Sea-disturbance (1 to 9). Z.—Calm.

Extract from Beaufort Scale, with Additions.

1 = b = blue (sky).	6 = o = overcast.
2 = c = clouds (detached).	7 = r = rain, rainy.
3 = f = fog, foggy.	8 = s = snow.
4 = h = hail.	9 = t = thunder. Lightning.
5 = m = misty (haze).	

And a repetition (as r r) is for much of either character.

CORRESPONDENCE.

HAWORTH'S SYSTEM OF TELEGRAPHY.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—I have carefully perused the specification of Mr. Haworth's patent for telegraphing between distant places without conducting wires; and if the object of his multiple drawings and incomprehensible letter-press is to mystify, and so conceal the principle of his discovery, he has succeeded in one instance that I know of. A piece of information has come to my knowledge which may give your readers a key to the solution of this matter. Mr. Haworth asserts that he has sent telegraphic messages from London to Norwood by his new method. I am given to understand that when Mr. Cyrus Field was in London a few months ago, he made an offer of £1,000 to Mr. Haworth, if he would send a short telegraphic message to Norwood without wires, in the presence of several witnesses named at the time. A further offer was made jointly by Mr. George Peabody and Mr. Cyrus Field to guarantee to Mr. Haworth the sum of £100,000 for his patent, provided he would send a telegram across the Atlantic. Neither of these tempting offers were accepted. It may be that Mr. Haworth contemplates making more money by his invention than was offered by the gentlemen aforesaid; or mayhap Mr. Haworth would not satisfy an idle curiosity for the paltry sum of £1,000 (which he could have obtained without sacrificing a tittle of his patent right). Let the reason be what it may, I am not so verdant as to believe that these liberal offers would have been declined had there been any possibility of the challenges being accepted and the experiments satisfactorily performed. Sir, my opinion is (and I enclose my card in order to enable you to estimate what my opinion is worth) that Mr. Haworth's patent is a bottle of moonshine; but where he obtains the cash wherewith to prosecute his experiments in as absurd a theory as that of perpetual motion I am at a loss to divine. I hope it is neither directly nor indirectly out of the national Treasury.—Yours, &c., A THOR SON.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—As a practical telegraphist of some twenty-five years' experience, will you permit me to offer a few remarks upon the subject of Mr. Haworth's alleged most important discoveries. I have in my time witnessed many experiments with the view of proving the practicability of transmitting intelligence without the aid of insulated conducting wires, and amongst others those of the late Mr. James Bowman Lindsay. He took out a patent in 1854, for "a means of transmitting telegraphic messages by means of electricity through and across a body or bodies of water." The invention consisted of a method of completing the circuit of electric telegraphs through water, "without submarine cables, or submerged wires extending across such water, water being the connecting and conducting medium for the electric fluid." The two wires respectively connected with the battery and signal instrument on one side of the water were to be attached, "metal balls, tubes, or plates, placed in the water, or in moist ground adjacent to the water." The same arrangement was to be placed on the other side of the water, and the forward, as well as the returned current, passed between the respective plates. The inventor preferred to place the plates on one side of the water at a greater distance apart than the distance across the water; but in case this was not practicable, the battery power was to be augmented, and the size of the immersed plates increased (such is the case with Mr. Haworth's plan). It was also necessary to place the plates for the forward current opposite to each other, and the plates of the return current opposite each other, in precisely a similar manner as that adopted by Mr. Haworth.

Your obedient servant, OMICRON.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—It would have been more acceptable (to your readers, at least) if your contributor "B. M." had continued to bewilder the aforesaid with his by no means new theory of force and form, instead of indulging in the doubtful experiment of trying to comprehend a system of telegraphy which, as he cannot fathom, he certainly ought not to ridicule. It is a certain indication of ignorance, and betrays a contracted grasp of intellect, and possibly the possession of mental powers dwarfed to lilliputian dimensions, when would-be clever persons strive to put the extinguisher of ridicule and sarcasm upon that which is beyond their grasp. "B. M."—the clever adept in the art of bewildering when dwelling on subjects of a recondite nature—should be the last person in the world to complain of being bewildered by Mr. Haworth, or any one else. My dear Sir, you *are* "*not* infallible," as you say; probably you are the same distance from that point as most of us, possibly a little more remote. Your contributor however, is candid—he confesses his ignorance. That is more than some will do, but, unfortunately, his ignorance is not characterised by anything of a commendable nature, since because *he* cannot see, ergo, Haworth and his system must be all humbug. Humility, modesty, and unassumingness become a philosopher.

Before any man blow the cold wind of incredulity upon a project, he should not only not understand how it can be done, but he should prove *de facto* that it cannot be done; and unless he is prepared to do this, it were more becoming for him to end his fruitless efforts of trying to comprehend the (to him) incomprehensible, by silence, coupled with renewed efforts; and by the reflection, that could our ancestors of a century back again "revisit the glimpses of the moon," they would esteem as little short of miraculous the way in which we have subjected the elements to our control, and made them our bond-slaves; and if in one short century, or, rather, half a one, such gigantic strides have been made, who shall put a limit to man's inventions and discoveries, and say, "hitherto shalt thou come, and no further." The womb of the future is big with great results, but it is the nature of man to grow conservative. Thirty years ago the staid conservative electricians of the present day would have been looked upon and were esteemed as the wildest of Utopian visionaries. But the science of electricity having been established, and grown to its present proportions, with a thoroughly organised staff of doctors, professors, and the rest, with whom all wisdom dwells, and who have a special privilege to dabble in its reconditics to the exclusion of every one else, as lawyers dabble in legal subtleties, and parsons in divinity—these eminent men are as much horrified, in their turn, at any innovation as were our aforesaid ancestors, who held the study of electrical science to be a tampering with the powers of darkness. And—necessarily being the repertories of all electrical knowledge, and the storehouse, to boot, from which all future discoveries in that line must emanate—what can be more presumptuous than the alleged discoveries of those outside the charmed circle; nay, what can be greater proof of the worthlessness of their boasted discoveries and inventions than the fact of their being outsiders, or, at best, interlopers, innovators, and that nondescript article which all good staid conservatives must treat with ineffable contempt? Can any good thing come out of Nazareth? And can any new discovery, or a deeper insight into known laws, and a more perfect adaptation of them in given circumstances, to accomplish given results, emanate save from the privileged class who assume to wear the mantle of wisdom, and something more? Where is your diploma, Sir? History continues to repeat itself, and will do so, I suppose, to the end of the chapter. The foremost people of this nineteenth century are fighting the battles of the scientific ages, and scientific men, when they find a science respectably established, and themselves smug doctors or professors therein, at once relapse into the chrysalis state, and spend the remainder of their days in admiring and experimenting upon the beautiful interior of their shell, the limit of which they believe bounds the horizon of human attainments; and philosophy even lends herself to assist in the same self-delusion. And hence it is that the car of progress, whether scientific or otherwise, is propelled mainly by laymen, who wear not the cloth, and with whom the chartered and orthodox would rather not hold communion, forgetful all the time that those truly great men, who helped to drop their lines in such pleasant places, and whom they have to thank for their goodly heritage, and all they know, to boot, were once heterodox, and perhaps, in the opinion of their contemporaries, dabblers in the black art.

"B. M." cannot see how Haworth can do it. His apparatus is an enigma to him. He cannot see how the results alleged to have been obtained by the elaborate arrangement are arrived at. It is not in consonance with known electrical laws, or appears not to be so, and hence he is incredulous, and pronounces the thing an absurdity. This is taking high ground. The writer assumes to have attained the *ultima thule*, and beyond that, of course, there can be nothing but the deluge.

I confess Mr. Haworth's method is a riddle to me. I cannot understand it, and to attempt to get an insight into the *modus operandi* by means of the specification of his patent is like, to use a homely phrase, "looking for a needle in a bottle of hay." For the sake of the metaphysician with the barbarous cognomen I wish it were otherwise. I know Mr. Haworth, and have conversed with him upon the subject, and, indeed, he has attempted to explain to me some of the principal features of his system; but as I have not been privileged to see it in actual operation, I am free to confess I am very little wiser. Nevertheless, I should hardly deem myself justified in doubting the validity of Mr. Haworth's word, as to his having been in constant electrical communication, by means of his own system, with a friend at the West-end, himself being at Brighton; far less should I deem myself warranted in ridiculing such a system, although the results may appear incredible.

Mr. Haworth is an earnest man, is no wag, and is certainly very jealous for the maintenance of the patent laws in all their integrity; and, indeed, it would not be waggery, but sheer madness, for any man to spend a fortune, and waste the best years of his life, in the development of a project if satisfactory results had not been obtained long ago. For myself, I do sincerely believe they have been obtained; and I am not a credulous individual, otherwise I might, on the representations of some well-meaning friends, believe myself legal heir to a dukedom.

"B. M." may rest assured "there are more things in heaven and earth than is dreamed of in his philosophy," not excepting the electrical part of it. And he would be a far cleverer man than either Faraday, Joule, or any of the other eminent names that adorn the annals of the nineteenth century, whose mental calibre should take in at one comprehensive grasp the height, length, breadth, and depth of any one science, and see its intricate laws laid bare and readable as the open page of a book. There are parts of the mysterious volume they never see, which are yet revealed to humbler minds. E. F. G.

INDIA-RUBBER CABLES.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—"The Manufacturers of the Core" seem to have trodden on Mr. Henley's corns, or else that gentleman fancies they have, his letter having been written, as anybody may see, while he was afflicted with a spasm of

asperity. It is a great pity objectionable personalities should creep into these matters. Nor do I think Mr. Henley would write such a letter as that which appeared in your last number in his moments of quiet, calm consideration. There is not one of your readers who has any knowledge of the matter that would endorse Mr. Henley's view that these gentlemen wanted to "shift the blame on to his shoulders." The fact is, both the one and the other may save their breath to cool their porridge, if they ever regale on such vulgar fare. "The Manufacturers of the Core" can hardly find fault with Mr. Henley, nor need Mr. Henley commit himself to the making of sweeping assertions in order to avenge an imaginary injury. As an accidental and impartial witness to the sheathing of the core in question (or at least a part of it), I am quite satisfied that the yarn was applied too soon after its emersion from the tarpot—I merely state a fact, be it understood, and do not enter upon the question whether this would or would not be injurious to the core—but in all fairness I am bound to admit that Mr. Henley was not responsible for this. The work was let out, I believe, from head-quarters to a gentleman whom we may term a concessionaire; probably he did not know a vast deal about this sort of thing, and anyhow he was impatient to have the cable finished, so that really sufficient time was not allowed to admit of the tarred yarn getting in a proper condition. The fact is, Mr. Henley and his men were in an awful stew about this bit of a job; the "dam boys" burnt the tar, and in their haste to get the yarn on the bobbins great bunch knots were tied in it half as big as one's fist to look at, instead of the strands being joined separately, and in their haste to get it off the bobbins on to the core, it was certainly applied in some instances in a comparatively seething state; and if there is any doubt about this, one had only to examine the cable when sheathed to find the tar oozing out between the spirals of the iron wire. But, as before stated, Mr. Henley could not help all this. If the gentleman concessionaire *must* be off to the Continent by a certain time, and *must* see the cable finished first, why Mr. Henley had no alternative but to do the best he could with it in the short time allowed, and it is quite unnecessary for him to state the reverse of all this in order to clear himself, since he was not responsible; nor can I conceive why he should don a cap which was never intended for his worthy head, as I think. Moral—for Government officials and others to cogitate over: Never hurry an important work like the manufacture of a submarine cable, and avoid creating a concessionaire, no matter how many dear old chums you may have, for "too many cooks spoil the broth."

Now a word to the "Manufacturers of the Core." You, gentlemen, I believe, have taken out a patent for the manufacture of submarine cables, which, so far as the core is concerned, has to be treated in a peculiar manner in order to obviate the serious objections hitherto in the way of the adoption of india-rubber cores. I have read the specification of your patent, and am of opinion that your mode of manufacture is the only safe one to ensure good and permanent cables made of this material. May I respectfully ask if the core of the cable in question was made according to your patent? and if not, why not? It is immaterial whether these queries are answered or not. I have the best possible answer in the possession of a piece of the core, which I have dissected from centre to circumference, and find it is *not made according to your patent*. A little bird whispers that you had no choice, that the gentleman under whose supervision the cable was made had his own peculiar notions, and that if you made the core at all it should be done rigidly to the letter of his instructions. Certainly, if this be so, it exonerates you from all blame, if the core is really showing symptoms of decay. But would it not have been wise under the circumstances to have stated that you had departed from your patent in certain particulars, and thus have prepared the public in an indirect way, that the onus of failure should not fall upon you. I conceive that you owed it to yourselves as manufacturers, and to the cause of india-rubber insulation, which you not unreasonably deem the palladium of submarine telegraphic failure, to have warned the public that you not only objected to the use of tar and iron sheathing, but that the core was made under protest, being a departure from what you consider the only safe mode of treating india-rubber when applied to that purpose.

We shall doubtless all willingly make allowances from Mr. Henley's misstatements of well-known facts. He says, "If tar caused the mischief, then they have themselves to blame for causing it to be used." And again, "Why did the specification compel me to use it (tar)?" Mr. Henley ought not to require to be told that he did *not* cover the cable for the "Manufacturers of the Core." Everybody knows that when they delivered the core at Mr. Henley's works they had nothing further to do with it; that the order for the core and the sheathing were *two distinct specifications*; and that the "Manufacturers of the Core" had no more to do with dictating what should be used in the serving than your humble servant, the writer of this. This is either unaccountable ignorance, or else the acme of disingenuousness, and the use of illegitimate weapons to cut and thrust out of sheer bad temper. The same may be said of the general sweeping assertions of your correspondent, which of course your readers will accept for as much as they are worth. The letter has every appearance of having been written under inspiration. With respect to india-rubber, practically Mr. Henley can know nothing about it, notwithstanding his broad assertion that he has "watched it carefully for years;" but of course he is wise in his generation. Who would not go with the stream? Certainly "india-rubber stands no chance against gutta-percha." I might just as well try to outbid Crœsus; but what if I should go on 'Change on an equal footing with the millionaire? The fact is, superiority goes for nothing here. We have to thank the "immeasurable superiority" (save the mark) of gutta-percha for the present deplorable condition of submarine telegraphy—bankrupt schemes, emasculated dividends, universal collapse, and no long cables—oh, yes! this golden dream of "immeasurable superiority" (and it is a golden reality to a few), I would it were true for the sake of a better though more modest insulating agent. The almost universal failure of gutta-percha has been the greatest difficulty in the way of india-rubber cables. It has shaken public faith in telegraphic enterprise, and so kept a worthier rival out of the field; but it is time the film of delusion was torn away from the eyes of a credulous world. Well, and what next? Why Mr. Henley has used 7,000 miles of gutta-percha wire, and will use nothing else if he can choose. I should think not, indeed; nobody expects he will be so green. But it would be doing a real service to your readers and the public if Mr. Henley would say how many miles of cable have failed, and how many are in work, of his laying. There is always a vast parade made of the number of miles of wire made and laid, but the statement is out of all proportion to what we know to be the actual mileage in working order; they should at least be candid, and show the other side of the ledger.

But bless you "gutta-percha never fails"—at least, you know, if—we have Mr. Henley's word for it, and he might as well have left out the qualifying "if;" and he is "very sorry to be obliged to run down india-rubber." Make your mind easy, my friend, upon this point, and allow me to congratulate with you that it is out of your power to perform the feat, being a handicap in which you or any one else having the hardihood to venture would be certain to come off losers.

With all deference to Mr. Henley's experience, your readers will hardly be reassured as to the effects of tar in gutta-percha; for the sake of the shareholder in posse and in esse, I hope he is right. BEPPO.

THE ORGAN OF THE TELEGRAPH SERVICE.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—Pardon me if I am out of place in referring to a matter that cannot have failed to strike the attention of others beside myself. In looking over the columns of the railway journals and other class papers no one can fail to perceive that these organs receive considerable support and countenance from the principal companies or firms engaged in the business represented. On reference to your columns, Sir, I note a total absence of companies' announcements. I have had some experience in the publishing department of a newspaper, and I am aware that the patronage of some people fetters and retards the exercise of the editorial functions; but I think at least that the telegraphing companies, the telegraph manufacturing companies, and others, having nothing to fear from honest criticism of their acts, should recognise the *Telegraphic Journal* as the organ of the service by keeping advertisements in a conspicuous position of your valuable paper.—I am, Sir, yours respectfully, AN OBSERVER.

LAW INTELLIGENCE.

SPENS v. WILLETT. THE UNITED KINGDOM ELECTRIC TELEGRAPH COMPANY (LIMITED), GARNISHEES. ATTACHMENT OF SHARES. IMPORTANT POINT.—This case came on for hearing in the Lord Mayor's Court, on Thursday last. Mr. O. B. C. Harrison for the plaintiff, sought to attach certain shares which were registered as the property of the defendant in the Company's books. Mr. Salter, for the Company, urged that the plaintiff could not attach the shares, as they were absolutely the property of defendant. His Lordship saw considerable difficulty in the way. Mr. Harrison was willing to accept the shares, if defendant would consent to transfer them. His Lordship found that certain stocks and public securities were exempt from attachment by act of parliament, and that was certainly in favour of the argument that other securities in the act were liable. Mr. Salter asked how many shares the plaintiff would take at par. The debt was £81. 11*s*., and the shares were £5. It was then agreed that 16 shares should be attached, subject, if necessary, to the opinion of the Court above.

TELEGRAPHIC NEWS.

TELEGRAPH CLERKS' PROVIDENT FUND.—Her Royal Highness the Princess Louis of Hesse has become a patroness of the above Fund, and has subscribed the sum of £5 to the institution.

EXTENSION OF THE ELECTRIC TELEGRAPH.—By a telegram from Suez we learn that the King of Ava has granted a concession for the introduction of railways, electric telegraphs, and steamboats into his dominions.

GOVERNMENT RETURNS RELATING TO ELECTRIC TELEGRAPHS IN INDIA.—Statement of the entire expenditure in England on account of electric telegraphs in India, viz., on purchase of stores, freights, instruction of assistants, passage money, &c.—In the year 1852-3, £30,475 12*s*. 1*d*.; 1853-4, £48,215 18*s*. 11*d*.; 1854-5, £1,871 13*s*.; 1856-7, £43,951 6*s*. 4*d*.; 1857-8, £114,346 19*s*. 10*d*.; 1858-9, £23,071 1*s*. 9*d*.; 1859-60, £2,014 10*s*. 2*d*.; 1860-1, £25,598 14*s*. 4*d*.; 1861-2, £95,869 15*s*. 6*d*.; £385,415 11*s*. 11*d*. Less recoveries in 1855-6 in excess of expenditure, £15 8*s*. 9*d*. Total, £385,400 3*s*. 2*d*.

A Telegraphist Honoured.—It is stated that Professor Morse, the inventor of the well-known instrument bearing his name, has had six orders of knighthood conferred upon him by the various Sovereigns in Europe.

The Persian Gulf Cable.—It was published in the daily papers of last Monday that the cable had parted. We have made enquiries in well-informed circles but have failed to obtain any satisfactory evidence corroborative of the report.

Telegraphic Connection of the whole of the Greek Islands.—An Athens letter states that Mr. Bufleb, the Levant Submarine Telegraph Company's agent at Scio, has made the Hellenic Government, on behalf of the Company, an offer to connect Athens telegraphically with Alexandria, Malta, and the whole of the Greek Islands, on either of the following terms:—(1) That, in consideration of a thirty years' concession, the Company would lay the necessary cables, pay all the working expenses, and transmit the Government's messages free; or, (2) that the Company, as before, laying the line, the Government should pay the working expenses, and the profit arising from traffic be equally divided between the two. The offer had been favourably entertained, and was to be submitted to the National Assembly for its consideration.—*Malta Observer*.

A Telegraph Clerk Tried for Manslaughter.—Jones Yendoll was charged at the Monmouth Assizes, on the 5th instant, upon an indictment and a coroner's inquisition, with the manslaughter of John Williams, at Aberystwith. The prisoner was the telegraph clerk at the Aberbeeg station on the Western Valleys Railway. The deceased was the driver of a passenger train on that line, and was killed, together with one William Worthing, through a collision that occurred on the line between Aberbeeg Junction and Victoria Station, by the meeting of the passenger train and a pilot engine and a goods train, about two miles from Aberbeeg and half-a-mile from Cwm, on the 17th of March. The railway is worked between Aberbeeg and Victoria with a single line of rails, and the rules of the company provided that the telegraph clerk should not allow a train to leave Aberbeeg for Victoria without first telegraphing to see if the line was free. The prisoner's negligence was alleged to be that he gave a pass to the guard of the up passenger train without receiving one from the guard of the goods train and pilot engine. He had, in addition to his duties as telegraph clerk, to issue tickets and make up his accounts in respect of all trains during every day of the week, not excepting Sundays, and he had also to attend to the parcels department. There were sixty or seventy trains a day to be worked by telegraph. The learned judge summed up, and said that persons must without doubt perform any duties they undertake, but the jury must be satisfied, in order to convict the prisoner, that there was a culpable omission on his part to perform his duty. The jury found the prisoner Not Guilty.

MISCELLANEA.

The Nobleness of Labour.—Labour, for a fair remuneration, whether of the brain or hand, should be the glory of any country; besides, there is true dignity in labour, especially in cultivating the soil. The object which the farmer has in view is to subdue the earth, to eradicate the briers and thorns, and to plant in their stead what is useful and beautiful to man. "Labour," says a noble worker, "has been made by Nature the law of man's condition. It is the price at which whatever is valuable in life must be earned. Whatever, therefore, degrades labour as the business of life, or renders it distasteful or dishonourable, does violence to our social laws no less than to a wise economy." All improvement—all progress of the race in civilization, has been the result of intelligent labour. It has built our cities, dug our canals, constructed our railroads, developed our lead, copper and iron mines, built our steamers and ships, given life and energy to the industrial arts, and, above all, is feeding and clothing our people and providing for their happiness. "The nation," says Dr. Samuel Johnson, "that can furnish food and raiment, those useful commodities, may have her ships welcomed at a thousand ports, or sit at home and receive the tribute of foreign countries, enjoy their arts or treasure up their gold." Let all labour, therefore, be crowned with honour; that labour, especially, that contributes so much to the welfare of man.

Appearance of the Sun from the North Pole.—To a person standing at the north pole the sun appears to sweep horizontally around the sky every twenty-four hours without any perceptible variation during its circuit in its distance from the horizon. On the 21st of June it is 23° 28′ above the horizon, a little more than one-fourth of the distance to the zenith, the highest point that it ever reaches. From this altitude it slowly descends, its track being represented by a spiral or screw with a very fine thread, and in the course of three months it worms its way down to the horizon, which it reaches on the 23rd of September. On this day it slowly sweeps around the sky with its face half hidden below the icy sea. It still continues to descend, and after it has entirely disappeared it is still so near the horizon that it carries a bright twilight around the heavens in its daily circuit. As the sun sinks lower and lower, this twilight gradually grows fainter till it fades away. On the 20th of December the sun is 23° 28′ below the horizon, and this is the midnight of the dark winter of the pole. From this date the sun begins to ascend, and after a time his return is heralded by a faint dawn which circles slowly around the horizon, completing its circuit every twenty-four hours. This dawn grows gradually brighter, and on the 20th of March the peaks of ice are gilded with the first level rays of the six-months' day. The bringer of this long day continues to wind his spiral way upward till he reaches his highest place on the 21st of June, and his annual course is completed.

Some New Facts in Relation to the Sunbeam.—The boundless extent of physical science is forcibly illustrated in the study of the sunbeam. What could seem more simple at first sight than a ray of light? And yet it would require long study to learn all that has been ascertained in relation to it. First was Newton's discovery that the white ray might be split into seven brilliant and beautiful colours. Then it was found that the ray was a compound of three elements—light, heat, and the actinic rays—those which produce the changes in the photograph and effect all other chemical actions of the sunbeam. Finally, within these few years has come the great discovery that the light produced by burning different substances is not only different in appearance, but when spectra are formed by passing these different kinds of light through a triangular prism, the spectrum of each element is crossed by lines peculiar to itself. Consequently, however far light may travel, it bears in its constitution the evidence of its origin, and thus brings to us from the sun and from the stars a knowledge of the substances which are glowing in those distant bodies. Each of the three elements of the sunbeam—light, heat, and the actinic rays—has been subjected to a great number of minute and delicate observations, and many curious facts have been learned in relation to each. Among other things, it has been found that some substances which allow light to pass freely through them are almost wholly impervious to heat. Professor W. A. Miller has recently been engaged in ascertaining a similar series of facts in relation to the actinic rays. He finds that the same law applies to these: bodies which possess an equal power of transmitting the luminous rays vary very much in their power of transmitting the chemical rays. This is an important fact in photography, as it is desirable to have the lenses of photographic cameras constructed of substances that will transmit a large proportion of the actinic rays. Of all the substances examined by Professor Miller none was found to surpass rock crystal in diactinic power. Water, ice, and white fluor-spar rival it, and pure rock-salt approaches it very closely. None of the different varieties of glass transmit rays extending beyond one-fifth or one-sixth the range afforded by quartz. A plate of glass less than 1-100th of an inch in thickness cuts off these rays almost as completely as a plate of twenty times the thickness. The vapour of water transmits the actinic rays freely, although it is extremely impervious to those of heat. Of the liquids examined, water is most diactinic, and next in order alcohol.

Heat Produced by Different Kinds of Fuel.—Several men of science have undertaken series of experiments to ascertain the exact quantity of heat developed in burning a given quantity of various substances. The most satisfactory of these experiments are those of Andrews, and those of Favre & Silbermann. Andrews inclosed the substance to be burned, together with just the quantity of oxygen required to burn it, in a close copper vessel with thin walls, and immersed this vessel in water—the water being carefully weighed. The substance was then set on fire by an electric current, and the temperature of the water was measured before and after the burning by a thermometer so delicate that it indicated $\frac{1}{300}$th of a degree. The apparatus of Favre & Silbermann was essentially the same, though they adopted some extra precautions to guard against the influence of the external atmosphere. The table below gives the results obtained by these two experimenters. It will be observed that the rise in the temperature of the water is given in degrees of the centigrade thermometer, which may be reduced to Fahrenheit degrees by multiplying the amount by 9 and dividing by 5:—

Substances burned.	Heat Units. Pounds of Water raised 1° C. by 1 lb. of each Compound.	Pounds of Water raised 1° C. by Combination of 1 lb. of Oxygen.	Compound formed.	Observer.
Hydrogen	34,462	4,307	HO	Favre & Silbermann.
Hydrogen	33,808	4,226	HO	Andrews.
Carbon	8,080	3,030	CO_2	Favre & Silbermann.
Carbon	7,900	2,962	CO_2	Andrews.
Sulphur	2,220	2,220	SO_2	Favre & Silbermann.
Sulphur	2,307	2,307	SO_2	Andrews.
Phosphorus	5,747	4,509	PO_5	Andrews.
Zinc	1,301	5,285	ZnO	Andrews.
Iron	1,576	4,134	Fe_3O_4	Andrews.
Tin	1,144	4,230	SnO_2	Andrews.
Copper	602	2,394	CuO	Andrews.
Carbonic oxide	2,431	4,253	CO_2	Andrews.
Carbonic oxide	2,403	4,205	CO_2	Favre & Silbermann.
Protoxide of tin	521	4,349	SnO_2	Andrews.
Suboxide of copper	256	2,288	CuO	Andrews.
Marsh gas	13,063	3,266	—	Favre & Silbermann.
Marsh gas	13,108	3,277	—	Andrews.
Olefiant gas	11,942	3,483	—	Andrews.
Olefiant gas	11,858	3,458	—	Favre & Silbermann.
Alcohol	6,850	3,282	—	Andrews.
Alcohol	7,183	3,442	—	Favre & Silbermann.
Ether	9,027	3,480	—	Favre & Silbermann.
Oil of turpentine	10,852	3,294	—	Favre & Silbermann.
Bisulphide of carbon	3,401	2,692	—	Favre & Silbermann.

The Lenoir Engine.—The engine invented by M. Lenoir, of Paris, under the auspices of the Imperial Gas Company of that city, and now in extensive use there, is thus described:—The Lenoir engine is in appearance and style very much like a horizontal steam engine. The cylinder has the necessary slide arrangements for the admission of gas and atmospheric air in due proportions. The gas is ignited by an electric spark from a battery connected by insulated wires, to each end of the cylinder. The daily cost of gas and chemicals is trifling; there is no boiler and no chimney. It can be worked on any floor of a house, and almost under any circumstances. As soon as the work required of the engine is completed, the gas is turned off, and the engine ceases. The saving effected by this engine over ordinary steam engines is estimated at 75 per cent.

The Science of Chemistry.—This science is not only of advantage to agriculture, physics, mineralogy, and medicine, but its phenomena are interesting to all men. The applications of this science are so numerous that there are few circumstances of life in which the chemist does not enjoy the pleasure of seeing its principles exemplified. Most of those facts which habit has led us to view with indifference are interesting phenomena in the eyes of the chemist. Everything instructs and amuses him; nothing is indifferent to him, because nothing is foreign to his pursuits; and nature, no less beautiful in her most minute details than sublime in the disposition of her general laws, appears to display the whole of her magnificence only to the eyes of the chemical philosopher. All material bodies are the subjects of chemical research. The solid and fluid matter composing the terraqueous globe which we inhabit, also air, light, and heat, are subjects proper for the examination of the chemist. The arts of dyeing, bleaching, tanning, glass-making, printing, working metals, &c., are purely chemical. The vegetation of plants and some of the most important functions of animals have been explained upon the principles of chemistry. By means of this science agriculture and gardening have been greatly improved. Chemistry directs the labours of the husbandman and the rural economist. In the dairy milk cannot be kept sweet and fresh, and butter and cheese cannot be made, without skill founded on chemical principles. Cookery and the art of curing and preserving beef, bacon, hams, and all animal and vegetable substances, are entirely chemical. The art of brewing, distilling, and making all sorts of fermented liquors depends upon the principles of chemistry. In medicine and pharmacy great benefits have been derived from the discoveries of chemical philosophers. The chemist resolves bodies into their elementary principles, and he examines their nature and properties when in a detached or simple state. He thus discovers their mutual relation to one another, and can recombine them in proportions different from those in which they were originally united. Hence new and useful compounds may be formed which nature does not produce. But chemistry is not only valuable as an art which supplies many of the wants, comforts, and luxuries of life. Its objects are sublime and beautiful in other senses; for it is intimately connected with most of the phenomena of nature, as clouds, rain, snow, dew, wind, earthquakes, &c.

"Visible Speech."—Mr. A. Melville Bell, well known in Edinburgh and elsewhere as an accomplished elocutionist, seeks to introduce what he considers a new art—that of "visible speech," by which every language may be made universally legible exactly as spoken. This he believes he has accomplished by means of "self-interpreting physiological symbols, based on a discovery of the exact physiological relations of sounds;" and, holding that his invention is one of "cosmopolitan interest and importance," he seeks to introduce it to the notice of "the representatives of Governments, as the proper patrons of a Universal Alphabet." He offers personal demonstrations of his system; and from a test afforded us, it certainly appears worthy of patient consideration and investigation. In the sort of prospectus he has issued for the purpose of introducing the scheme to the attention of Governments, Mr. Bell says:—"The alphabet of physiological symbols now invented presents, as it were, pictorially to the eye all the organic relations of the elementary sounds, and in these exhibits at a glance the principles which govern the mutations of letters and sounds in passing from language to language, and so casts a flood of light on the secrets of etymology; and that, by a peculiar feature of the invention, all the sounds of every language are represented by so small a number as thirty-four types. The number required for the printing of any one language is, of course, smaller. The English language, for instance, requires only twenty-two types for the most minutely accurate phonetic symbolisation of all its vowels and consonant elements. This apparently marvellous result has been attained through a physiological discovery of the exact formations, and of the mutual relations, of linguistic sounds. Among its practical applications he suggests the following:—"The electric telegraph will deliver its messages with the exactness of *viva voce* utterances. Despatches may be transmitted in any language, through any country, and no necessity for translations can ever arise. An English clerk would manipulate a message in Russian, Hindustani, or Chinese with the same facility that he would one in his own tongue." He adds that "no instance of failure has occurred in the perfect symbolisation of the most difficult words selected from the following languages:—American, Indian, ancient Greek, Arabic, Danish, English, French, German, Hindee, Hungarian, Italian, Latin, modern Greek, Persian, Polish, Portuguese, Russian, Scottish, Spanish, Urdu." He says:—"The applicability of the physiological symbols to Chinese, or to any other language (or dialect), will be demonstrated to competent investigators;" and furnishes credentials referring to the above nineteen languages, which leaves no room for a doubt of the universality of the invention.—*Scotsman.*

Novel Lightning Conductor.—This invention consists in a conductor composed of a continuous strip of copper without any joint, unless to form the tip or point, placed close against the building or structure to be protected without insulation, and secured thereto by strips of the same or other metal placed across it and nailed to the building or structure. It also consists in a novel mode of forming the tip point of such a conductor from the strip itself, thereby making it entirely continuous from end to end.

Inventors and Inventions.—Let us not cheapen inventions, but be kind and encouraging to the inventors; beware of killing the goose that lays the golden egg! Many inventors die before the hour of triumph; others falter on the way. Invention is a struggle, a conflict, almost a battle; if the victors are rewarded, the dead are honoured and the wounded carefully attended to. Glorify the inventors who succeed; cover with an indulgent self-respect the faults of those who fail; and soothe the last years of the wounded—those invalids of industrial science who have known only the pains of the fight, and always remained ignorant of the joys of victory.—*Dumas.*

Gun-cotton.—Professor Abel, who has so carefully investigated the properties of gun-cotton, thus sums up the peculiarities of this explosive substance:—"When inflamed, or raised to a temperature ranging between 137° and 150° centigrade, it burns with a bright flash and a large body of flame, unaccompanied by smoke, and leaves no appreciable residue. It is far more readily inflamed by powerful percussion than gunpowder; the compression of any particular portion of a mass of loose gun-cotton between rigid surfaces will prevent that part from burning when heat is applied. The products of combustion of gun-cotton redden litmus, and contain nitric oxide, hence they have a corossive action on gun-metal. In the open air it may be inflamed, when in actual contact with gunpowder, without igniting the latter; in a confined space (as in a shell, or the barrel of a gun) the almost instantaneous rapidity of its explosion produces effects which are highly destructive, as compared with those of gunpowder, while the projectile force exerted by it is comparatively small." For these reasons Professor Abel—who is chemist to the War Department—does not think we are yet in a position to use gun-cotton as a substitute for power.

The Magnetism of Iron Ships.—The following conclusions appear to be pretty well established, in respect to the deviation of the compass and the magnetism of iron ships, viz., that the magnetism of iron ships is distributed according to precise and well-determined laws; that a definite magnetic character is impressed on every iron ship while in the building slip, which is never afterward entirely lost; that a considerable reduction in the magnetism of an iron ship takes place on first changing her position after launching, but afterward that any permanent change in its direction or amount is a slow and gradual process; that the original magnetism of an iron ship is constantly subject to small fluctuations from change of position, arising from new magnetic inductions; and that the compass errors occasioned by the more permanent part of a ship's magnetism may be successfully compensated—this compensation equalizing the directive power of the compass-needle on the several courses on which the ship may be placed. That law is implanted in *all atoms* of nature, with a greater and less force, and is exhibited according to *the position* of those atoms—thus it pervades all nature is evident. Its action can be more plainly seen or read in iron than in any other inanimate matter. As it is seen in iron, so it must or can be seen in iron ships. Any one can prove this by a simple experiment with a bar of soft iron and a poised magnetic needle or compass. By holding the bar of iron perpendicular over the needle, they will find the iron will, with a force in proportion to the size and length of the bar, act as a magnet, and attract the "south" point of the needle, repelling the "north;" invert the bar and place it perpendicular under the needle, and you will have an *immediate* reverse action; place the needle in the middle of the bar (still perpendicular), and there is no force exhibited; lay the bar in a horizontal position, and it will "appear" to lose its force, the "polarity" of the bar is *then* in or through its diameter. Thus the action or exhibition of magnetism in the iron depends entirely on *its present position*, and has nothing to do with its former position, or how it has been. With a piece of steel it is different: *its atoms* being in a more compact position, its "polarity" may be set or fixed, yet its *position* must alter its force, but not to the same extent as iron. If the ship is built of steel, this theory will hold true: it would then be very important to know not only the *position* in which she had been built, but the latitude she was built in; yet an examination of the ship with a poised needle would show or explain. Thus *the cause* of a local attraction may be noticed *anywhere*. As that action is shown in iron, so it acts and can be seen or noticed in iron ships; hence it is not necessary to know how a ship *has been*, but what is *her present position*. Thus, "adjusting" iron ships in docks, and placing fixed magnets to counteract local attractions, cannot have the desired effect, as it (magnetism) pervades all nature, and cannot be counteracted, but can be known, and may thus be avoided.—*American Artizan.*

A Law of Combustion.—Numerous and careful experiments have developed the law that the heat generated by the burning of any substance is pretty nearly in proportion to the weight of oxygen with which the substance combines in burning. For instance, the combustion of one pound of hydrogen gas will raise the temperature of 33,808 lbs. of water one degree of the centigrade scale, while the burning of a pound of tin will raise the temperature of only 1,144 lbs. of water one degree. But the pound of hydrogen in burning, combines with eight pounds of oxygen, while the pound of tin combines with only about one fourth ($\frac{1}{4}$ths) of a pound of

oxygen. A simple calculation will show that the quantity of heat generated by the combination of a pound of oxygen is very nearly the same in both cases. A pound of oxygen in burning hydrogen will raise the temperature of 4,226 lbs. of water one degree, while in burning tin it will raise the temperature of 4,230 lbs. of water one degree. This law does not hold, however, in cases where the combustible in burning undergoes a change of form, from the gaseous to the solid, or from the solid to the gaseous state. For instance, carbon in burning to carbonic oxide is changed from the solid to the gaseous form, and in this case a pound of oxygen generates only 2,962 units of heat, while in burning this carbonic oxide into carbonic acid, where no change of form takes place, a pound of oxygen generates 4,258 units of heat. In burning zinc the oxygen is changed from the gaseous to the solid state, and in this case a pound of oxygen generates 5,285 units of heat. When either the combustible or the oxygen is changed from the solid to the gaseous form, a portion of the heat is absorbed, and the amount of sensible heat is diminished, but when the change is the opposite way the sensible heat is increased. Even where no change of form occurs in either of the combining elements, the amount of sensible heat developed may be modified by a change of volume; an increase of volume diminishing the sensible heat, and a contraction of volume adding to the heat set free. There are indications also that the law is further modified by influences which are not fully understood.

Specific Heat.—Different solids and liquids undergo different degrees of expansion, from the same quantity of heat; we have further to observe that equal bulks of different substances require the addition of different quantities of heat, to produce the same change of temperature. The heat entering in this manner into the composition of various substances, is called their specific heat, and may be thus conveniently illustrated:—Take a pint of water at 100°, and mix it with a pint at 50°, the thermometer will indicate the temperature of the mixture to be 75°, which is as might be expected, being the precise arithmetical mean; now mix a pint of mercury at 100°, with a pint of water at 40°, and it will be found that the resulting temperature is not the mean 70°, but 10° lower, viz., 60°, so that the quicksilver will lose 40°, whereas the water will only gain 20°; notwithstanding which, it is clear that the water has gained the whole heat that the quicksilver has lost; hence water has a greater capacity for heat than quicksilver, or it requires a larger quantity of heat to raise it to a given temperature. Again:—Take two similar glass bulbs, one containing water and the other mercury, and immerse them at the same time in hot water: it will be found that the mercury bulb is heated up to the temperature of the water, in half the time that the water bulb requires; and if the two bulbs, after having both attained the temperature of the water, be removed and exposed to the air, the mercury bulb will cool twice as rapidly as the other. All these experiments concur in proving that water has twice the capacity for heat that mercury possesses. What is termed the specific heat of water is not, however, as two to one. Since it is more convenient to express the capacities of different bodies with reference to weight than to measure, a pound of quicksilver at 40°, agitated with a pound of water at 156°, produces a temperature of 152°3: the water thus losing only 3°7 of temperature, and the mercury gaining 112°3. Now 3°7 : 112°3 :: 0·033 : 1; consequently if water be taken as the standard of comparison as unity, the specific heat of quicksilver must be called 0·033, or if, which is more convenient, the specific heat of water be taken as 1,000, then that of mercury will be 33.—*Noad's Lectures on Chemistry.*

PATENTS.

APPLICATIONS FOR LETTERS PATENT.

1853. G. Lansdown, a method of providing a direct communication between any guard and any passenger in a railway train.

1858. J. Lang, certain improvements in apparatus for signalling on railways.

1868. W. Dicey, an improved means of communication between railway guards or other attendants and passengers in railway trains.

1869. A. Alexander, improvements in firing or discharging and exploding missiles under water, and in constructing such missiles.

1873. W. Anderson, improved apparatus applicable to the working of moving parts of railway trucks, and of the signals connected therewith, and of other instruments required to be operated in a predetermined order.

1906. E. Tattersall, improvements in effecting communication in railway trains between passengers and guard.

1924. M. Woodfield, improvements in apparatus for communicating between passengers and guards and between guards and engine drivers on railway trains.

1940. G. E. M. Gerard, improvements in apparatus for cutting sheets or bands of vulcanized india-rubber and other substances into threads.

1973.—P. A. J. Dujardin, improvements in electric telegraphs.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

1787. Z. B. Smith, and W. L. Nelson, improvements in apparatus for signalling on railways.

1823. A. V. Newton, improvements in electro-telegraphic apparatus.—A communication.

PATENTS SEALED.

341. B. Todd, improvements in composition to be used to prevent the oxidation of iron, the fouling of ships' bottoms, and other submerged things, and also preserving wood from decay and worms.

PATENTS WHICH HAVE BECOME VOID.

1800. Sir W. O'S. Brooke, improvements in apparatus for suspending and insulating electric telegraph wires.

1819. R. Laing and G. H. Cossins, an improved mode of obtaining nitrous acid gas for making sulphuric acid.

NOTICES TO PROCEED.

821 J. Hunt, an improved instrument or "tell tale," for registering the time of arrival and departure of workpeople in houses of business and manufactories.

899. J. B. Thompson, improvements in electro-magnetic induction machines.

PATENT ON WHICH THE STAMP DUTY OF FIFTY POUNDS HAS BEEN PAID, AND DATE OF ITS PRODUCTION FOR CERTIFICATE.

1994. H. Wilde, improvements in electro-magnetic telegraphs, and in apparatus connected therewith.—Dated 10th August, 1861.

PRICES CURRENT OF INSULATING MATERIAL.

TO CORRESPONDENTS.

As information respecting Improvements, Extension of Lines, and Progress of New Undertakings will at all times be most acceptable, we hope that our readers will kindly render us assistance, by furnishing us with brief notices of events and occurrences in connection with electrical and scientific progress.

Communications intended for publication must be authenticated by the names and addresses of the writers; not necessarily for insertion.

Letters relating to Advertisements are to be addressed to the Publishers. All other letters and communications to be addressed to the Editor of the *Telegraphic Journal*, 4 & 5, Suffolk-lane, Cannon-street, London, E.C.

The *Telegraphic Journal* can be had of Messrs. Smith & Co., Strand; J. Onwhyn, Catherine-street, Strand; Messrs. Dawson & Co., Cannon-street, E.C.; Messrs. Kent & Co., Paternoster-row, London. Messrs. Heywood & Co., Manchester; at the various railway stations; and of all news-agents, &c., &c.; or it can be supplied, if preferred, direct from the Office on the following terms:—

Quarterly, 4*s.* 4*d.* | Half-yearly, 8*s.* 8*d.* | Yearly, 17*s.* 4*d.*

TO ADVERTISERS.

The *Telegraphic Journal* is the most effective medium for inventors, patentees, contractors, manufacturers of insulating materials and electrical apparatus to submit their various specialities to the consideration of secretaries and managers of telegraph or railway companies, and other persons engaged in electrical and telegraphic pursuits.

Clerks, assistants, manipulators, and instrument makers, seeking employment, &c., will find the *Telegraphic Journal* a ready means of making known their requirements.

Advertisements must be delivered to ensure insertion before Seven o'Clock on Thursday evening in each week. The charges for Advertisements are—

	£. s. d.		£. s. d.
Whole page	4 4 0	Quarter page	1 7 6
Half ditto	2 10 0	Four lines and under (single col.)	0 3 6

Single Advertisements from the country must be accompanied with stamps in payment.

FORCE AND FORM.

Contributed by B. O'M.

V.

It is considered that the ultimate particles or atoms, of which each simple substance is composed, were created of distinct and separate kinds, and that they are essentially distinct. If the ultimate particles of matter are hard and unalterable, then of course, this is a necessity; but with the atom just described it is not so. If all matter, of whatever kind be simply force in form, then the only essential differences will be, that of form, and this being essential to the simple atom, is essential to all other atoms of whatever degree, and also of the elements of matter in ultimates, and of all minerals, organic and animal matter; for that which is essential to the simple atom must be an essential to matter, however ultimated. We speak of the three kingdoms of nature as the mineral, vegetable, and animal, but really there are no such separate divisions in nature; convenient such divisions are, no doubt, as classifications for study; but as scientific facts, not true. One universal law binds all together. This is it:—Everything is what it is by virtue of its form.

This is not axiomatic, perhaps, in the ordinary acceptation, like these, "A thing cannot both be and not be at the same time," "The whole is equal to all its parts taken together," &c.; at least it is a universal proposition, and as such, if true, may be proved to be so; if not, disproved. Now mind, do not confound form with shape. Form is the *resultant* of internal potencies, not only as to balance, but as to intensity and rythm. Shape is the *result* of external circumstances. Internal potencies are two, polar and equatorial; but of intensity and rythm, infinite. External circumstances have no constant law, but are the effects of various laws. Let us see how the matter stands. As before, let us take the province of each sense and submit what it gives us to the solvent of reason, to try to find wherein its essence consists. We will take the sight first, as before. Colour and shape only belong to the sight, colour not being essential to matter it was not then touched; but shape only, shape being the particular of which form is the general: colour then remains. By means of light we have colour. Light is produced by the undulation of a very fine kind of matter called æther; by the way, how odd it is that people still continue to call light an imponderable substance, when it is now agreed on all hands that it is simply the motion of the æther; but the æther is matter, is it? Well, certainly, but the light is not the æther, but simply the motion of it; besides the æther does not belong specially to this earth, but is a universal sphere embracing all planets, suns, and comets; for light comes to us from the remotest star as well as from a tallow candle beside us. It is said that light is produced by the undulations of the æther; but this can hardly be; for undulations are reversed curves, which can result only from discontinuous and reversed force, and such a force can never arise from one source, or act from within: however, for the present we will leave that. Light, then, is produced by the internal motion of the atoms of the æther. If light come direct to us without refraction or reflection, it is colourless. If refracted, then according to the angle of refraction is the colour: whether red, yellow, or blue, or their intermediates. This has been called a separation of light into its compotent colours, as if three positive colours mixed together would make no colour at all. We have all heard of Lindley Murray's wonderful doctrine, that two negatives make an affirmative; but we have never heard or seen it stated, that three positives, when taken together, make nothing at all. Did you never go to a cram lecture, where the last discovery in science is shown to the wondering audience. There you might have seen this wonderful thing proved *a priori*. A disc of cardboard, painted with the spectrum proportions of red, yellow, and blue, fixed to a machine that it may be twirled round, so that the colours may be mixed to the eye, and you are told, that what you see is white; although you know very well, that it looks suspiciously like grey. O, but you know that is attributable to the crudeness of the colours used. It is a pity, that pure colours cannot be tried, that this assumption might be made a reality if possible. But if it were, what would it prove? Simply that colours have no real existence, which of course they have not, if light is simply motion, which hardly any one doubts now; the different degrees of refraction being mere modifications of that motion. If light come to us through vapour, as at sunset, we have the brightest red shading off into the most beautiful tints of orange, yellow, and apple-green, to the blue of the clear sky, and this by the modification of the motion, which produces colourless light; therefore the infinite varieties of tints observed in nature are all produced by modifications of the form of motion, which produces light; consequently form, and its modifications, internal and external, produce all visual impressions. Touch:—The properties of matter cognizable to the touch, not being generals, consequently not examined before, are—hard, soft, elastic, non-elastic, rough, smooth, and hot and cold. Hard and soft, and elastic and non-elastic, are modifications of resistance, or of the intensity, or balance of internal force, and not alterations of form. Rough and smooth are results of external shape; if from within, as in the husk of fruits, &c., then from internal form. If accidental, as from abrasions, &c., still the surface left will be according to the form of the ultimate elements of that substance, or from the intensity or balance of the forces which ultimate these forms. Hot and cold:—These properties cannot exist without modifying the form of the substance wherein they are, which modifications are called expansion and contraction; but these may not extend to the absolute change of the internal form, they may be simply modification of tension of force; but they may be modifications of form: as in water becoming steam or ice; therefore form and its modification, together with intensity and balance of force, produce all the impressions of touch. But intensity and balance of force, if pushed beyond a certain limit, produce alteration of internal form. Besides what is here noticed, form and resistance, or general properties referable to touch, which were noticed previously, are also included in the present conclusion.

Smell.—I will quote from my previous induction of the objects of the senses, to save the trouble of reference: "There can be no smell without effluvia; but what is effluvia? Philosophers say they are the finest and most volatile parts of matter, and, though they cannot be perceived by sight or touch, yet reason shows that without form and resistance they are not even conceivable." Therefore difference of scent means change of the form of such effluvia, and difference of intensity of scent means difference of intensity of the forces ultimating such forms.

Taste.—Taste is a finer touch, and that the tongue may feel with its internal parts, a natural solvent of all things to be tasted is poured out, that they may penetrate its interiors, so that it may feel the interiors of things with its interiors; but the lips and tongue have a more exquisite sense of touch proper than the fingers, and are used as organs of touch by children. The range of sensations derived from our tongue and palate is far greater than that derived from our touch proper, yet, as far as our sensations derived by touch from forms go, their names are given to the sensations of taste, as rough, smooth, hot, cold, flat, sharp, &c. Besides, in all cases where taste has been analysed the various tastes have been attributed to the ultimate particles of the matter tasted: as sharp, sour, acrid, have been attributed to angular particles; but sweet, bland, smooth tastes have been attributed to globular particles or a mixture of angular and globular. Whether this be so or not it does not much matter; but it shows clearly that taste and touch are considered but different degrees of the same sense. The taste supplements the touch. The touch feels the externals of things; but the taste feels their internals. It is superior to the touch in delicacy, even as to the proper province of touch, as well as extending into a region where ordinary touch cannot reach.

Hearing.—"Hearing is the effect of the tremor or gyration of the air;" therefore the different sounds heard from the different modifications of the forms of the semotions of the atmosphere. The modifications from grave to acute arise from the modification of form; and the gradations from loud to gentle sounds arise from variations of intensity of the force.

Each thing then is to us what it is by virtue of its form, and its range of potency in that form, by virtue of the intensity of the force which ultimates that form. If this be true, then all nature is organic, and there is no such thing as dead matter; but all material things are organs of life, from a stone up to man. One grand life pervades the whole in different degrees and series, according to each form of reception.

The next question that arises is, out of this one simple atom how are the infinite forms in Nature to be built up?

In the Newtonian theory there must be at least fifty solid atoms to begin the world with: one for each simple substance. That would make a considerable series, if arranged according to the laws of permutation; but things will not always be arranged in that way; there must be some affinity between them, or they will not unite. It is to be borne in mind that our atom is not an element; but each of these fifty is not only an atom but an element; and, by the way, an element can hardly be the simplest entity in Nature; at least, in the succeeding series of Nature there is no such grade of advance as that.

As stated above, all atoms, whether simple or compound, must be of similar nature; for they are all compounds of that first and simplest form of existence. According to the essence of this atom, as described and figured, two or more of these may unite polarwise, and, as it were, coalesce; but that would be only a concreting of simple atoms, it would not be an ascent to a new degree or form of atom. It is simply a concrete form, and not a discrete, or new form. To produce the next new form, or second atom, must be by the aggregation of the first atoms polarwise, and in a vortical, like to the fluxion of the first atom; so that each shall be joined to each by unlike poles in a continuous unending series, which must, of necessity, fall into the vortical form, else it would have no stability. You can conceive of it as a ring, like Faraday's ring magnet, or, perhaps what would be nearer, a ring of magnets, where the whole minus each in turn would form an armature to each; but you can also clearly see there would be no stability in this form; it would infallibly be disrupted by external force. Not so with the vortical, into which the atom naturally tends.

These simple atoms so aggregated would have, of necessity, somewhat changed their nature. Our suppositious ring of magnets will serve to explain this matter to us. Each atom being joined to the others next to it in the vertical series, the circumferential gyres of each cannot possibly exist; for the polar fluxion of each would join on to the polar fluxions of those next to it, and so complete the vortical fluxion of the series without return circumferential gyre; as there would be none needed or possible. Similarly would our ring of magnets have no external lines of force, if they perfectly armed each other. But let us state, generally, the fluxion of the magnetic force, so that this may be seen more clearly.

In a symmetrical magnet the internal and external lines of force are equal in amount though not in density; but if this magnet be bent round as a horseshoe and simply armed with a piece of iron, the external lines of force are nearly all removed, and if it were perfectly armed, there would be no external lines, the whole would pass through the armature to complete the circuit. Now this is just what must take place in our atom of the second order. The first atom is a simple vortical fluxion. The second is a spiral vortical, and the third will be a compound spiral vortical, and so on, according to each discrete degree. The first atom must be of infinite elasticity and mobility, from the very nature of its fluxion. The second will be less elastic, and less mobile, and comparatively more fixed and hard, and so on in each order of atom as they become more finited: and still more so of the elements.

THE CONSTRUCTION OF AN OVERLAND LINE BETWEEN BAGDAD AND FAO.

(From an Occasional Correspondent.)

Bagdad, 6th July, 1864.

You are, I have no doubt, already aware that our operations in Mesopotamia, as regards the construction of the land line from Bagdad to Fao, at the head of the Persian Gulf (the point where the cable is landed), have been very much delayed and obstructed by the revolt of the Montefic Arab tribe against the Turkish Government; the consequence is that we have only been able to construct the line from either end, viz., Bagdad and Fao. From Bagdad the line south is completed as far as Dewanich, a distance of 105 miles, with an intermediate station at Hilleh (Babylon); and from Fao northwards the line is completed to Gurneh (the confluence of the Tigris and Euphrates), a distance of about 105 miles, with an intermediate station at Bussorah, leaving a break in the chain of communication of about 180 miles, for which distance the line of telegraph will follow pretty closely the banks of the Euphrates, as soon as the Montefic rebels make peace with the Turkish Government.

In April a new sheikh was appointed by the Turkish Government in place of the rebel sheikh. After some fighting in Mesopotamia between the two parties, the rebel crossed to the right or west bank of the Euphrates, and was said to have gone away for good into the desert with a few of his followers, and the Turkish authorities were fain to believe that the matter was quite settled, and the telegraphic operations could be commenced at once; but, before the telegraph stores could be got on the ground, the rebel again makes his appearance on the west bank of the Euphrates with a strong force of Arabs, and the country is again very unsettled. But up to this time (with one exception, when a few insulators were broken) the rebels have not interfered with the portion of the line already constructed, which is a proof that their ill will does not extend to that, for with the greatest ease they could destroy the largest portion, and no one to say them nay. I only hope that the policy of the Turks may so far settle the matter as to allow the line to be finished next cold weather. But even with this break of 180 miles, with arrangements made by Colonel Kemball, Her Majesty's Consul-General at Bagdad, for Arab messengers to run between Bussorah and Dewanich, messages have been received at Bagdad, from India, in four and a-half days, and had the Turkish stations between Bagdad and Constantinople been supplied with European clerks, and that line in good working order, telegrams could easily have been sent through from India to London regularly in six or seven days, but up to this time there are no signallers for the stations.

It is very gratifying to know that the Gulf cable continues to work without interruption. Next month is the hottest in the Gulf; if the insulation keeps up during August I have no doubt, from what I know personally of the Gulf, that it will go on satisfactorily for years, as far as the cable itself is concerned. The difficulty in this part of the world is the land lines, and not the cables; but in Asia, I think, things are very often reversed; for instance, the Asiatic covers his head and uncovers his feet, while the European does just the reverse; the Asiatic writes from right to left, the European just the reverse; and so it appears in telegraph matters.

The land line from Bagdad to the Persian frontier, at Khannikeen, is completed (one wire), and the English staff are progressing with the line in Persia (one wire), but not so quickly as they could wish; they have a great deal of trouble to get poles, &c., which have to be supplied by the Persian Government. It was hoped that the line would be ready for work early in July, but I am afraid such will not be the case. The Persian line joins the Turkish line at Khannikeen, passes through Hamadan to Teheran, thence through Ispahan and Shiraz, to Bushire, where there is a cable station.

THE VOLTA-INDUCTOR OF SIEMENS, HALSKE, & CO.

THE core of this coil consists of varnished iron wires, 13 millimetres thick and 95 centimetres long, cemented into one cylinder of 60 mm. diameter. Round this core are coiled parallel, in two layers, two copper wires of 25 mm. thickness. Core and wire weigh 35 lbs., and are inserted into an ebonite (highly vulcanized india-rubber) tube of 26 mm. thickness at the ends, and 12 mm. in the middle. To this tube are fastened equidistantly 150 thin discs of the same material, dividing the whole length into as many compartments, each of which is filled up with thin copper wire, 0·14 mm. thick, covered with silk, and saturated with a suitable varnish. The total length of this secondary wire is 129,000 metres, making 299,000 turns round the tube; weight about 58 lbs. The resistance of the secondary wire is 162,000 Siemens' mercury units at the freezing point, and that of each of the primary wires 0·32. The reason the insulating tube is left thinner at the middle is, firstly, because the tension there is smaller under normal conditions, even = to O, and increases towards the ends, where the danger of the flying of a spark towards the core only can be diminished in proportion to the thickness of the insulating material, but principally because those layers of the secondary coil closest to the tube form a Leyden jar with the primary coil. The capacity of this double jar must be as small as possible, as otherwise the tension at the ends of a secondary wire with the iron core would considerably diminish the length of spark. No tension being in the middle, no destructive jar actions can take place. The most suitable form of insulating tube, therefore, is the parabolic section.

The primary wires should enter and leave the apparatus at the same end of the coil, and the battery be thus put in circuit so as to make the positive electricity of the secondary coil appear at the closed end of the coil, and the negative where the primary wires enter, for the spark always flies from the positive pole, and its striking distance is longer. If we allow the positive pole to be at the open end of the apparatus, the spark would, at long distances, prefer flying to the primary wire and coil, to the destruction of the instrument. The proper connexion is easiest ascertained by putting a commutator into circuit with one or two elements urging the spark at short lengths, and reversing the commutator if it should start from the long pole; or, if the operator be not quick-sighted enough, whichever connexion produces the longest spark is sure to be the right one.

The hollow disc *should always be connected with the negative* pole, for it then increases the length of spark, but diminishes it when put to the positive pole. Its action is twofold: first, by acting indirectly on the positive *point*, it increases the tension of the electricity starting from that point, and consequently the length of spark, but principally through its jar action with the walls of the room; it decreases the tension of the negative pole (incompletely conducts it off), by which means increased tension of the positive pole, and consequently length of spark is gained. It (the hollow disc) may be dispensed with by putting the pole to earth altogether, but this is not desirable at long lengths of sparks, for the too greatly increased tension of the positive pole would facilitate the passage of the spark to the core or into the air, and thus destroy the apparatus. Connecting a Leyden jar of sufficient thickness and very *slight capacity* between negative pole and earth produces nearly the same effect as the hollow disc. To produce a brilliant spark the inner coating of a Leyden jar of thick glass should be connected to the positive pole, the outer to the negative. By closely approaching the poles to one another a quick succession of brilliant discharges will take place accompanied by a shrill sound.

The condenser consists of tinfoil separated by varnished paper, each being 15,000 centimetres super. With Siemens' construction (differing from that of Ruhmkorff) it is of little influence as regards length of spark; it considerably diminishes the strength of the primary spark, and the flying about of the alcohol of their make-and-break apparatus.

This apparatus is constructed so as to make a *long contact* and a *short break*, and is put to work slowly swinging to and fro. The alcohol is poured over the platinum, amalgamating the contact-cups, and should be renewed when blackened by the oxide of mercury. The amalgam (silver amalgam will do as well) should be thickly fluid and free from oxide. One contact-cup serves for the self-acting and break arrangement, the other for the primary current. Before use the battery should be well cleaned and freshly amalgamated. The nitric acid must be strong, and, if necessary, one-third concentrated added to the mercantile, and should be filled only a quarter of an hour before the experiment. The deciding experiment, with battery *in good condition*, gave—

1	element length of spark	21 centimetres
2	" "	8·9 "
3	" "	47·5 "
4	" "	51 "
5	" "	55 "
6	" "	58 "

Using the primary wires parallel. With more elements, however, they might be joined more profitably into one length. It would be dangerous to attempt to produce sparks more than two feet in length. Sparks are seen flying off all pole-faces in the dark. This seems to be the approaching maximum. For experiments before the public, sparks between two balls (without disc), with six elements, at about 18″ or 20″ in length, show best.

DE LA RIVE ON THE PROPAGATION OF ELECTRICITY IN RAREFIED ELASTIC MEDIA.

IN the last part of the *Mémoires de la Société de Physique et d'Histoire Naturelle de Genève* which has reached this country there is a paper by this distinguished electrician.

M. De la Rive, after fully describing the apparatus employed, remarks that, in studying the general phenomena which the transmission of electricity through rarefied gases presented, it was found that, although when the circuit was composed of good conductors the rapid reversal of the current caused no deviation of the galvanometer; on the contrary, the circuit was interrupted when having to pass through a bad conductor, such as a rarefied gas—the direct current, under such circumstances, being alone transmitted, so that the direction of the induced current which traversed the gas was the same as the inducing one.

The pressure at which a discharge of a given intensity commences to traverse a gas varies not only with the gas and its degree of rarefaction, but also with the dimensions and form of the vacuum tube employed. Also, *the discharge does not pass immediately after the electrodes are placed in connection with the coil.* A certain time is required, which increases with the resistance, from whatever cause that resistance may arise. Thus, in a tube 30 to 50 centimètres long, several minutes are required, however rarefied the gas may be. When once the current has passed, however, the passage becomes more easy, and if the density of the gas be increased, it does not divert the passage of the current. The professor thinks, from these and other facts which he mentions, that the gaseous matter opposes a certain *inertia* to affect the peculiar disposition which the passage of the current induces, and which is determined by the tension preceding transmission.

Some numerical results are given to show the general truth of these observations, and the paper proceeds to deal at some length with the well-known stratification of the electric spark. It is remarked that the transmission of electricity through the tubes determines a movement in the particles of the gas, and a movement which seems to be an impulse emanating from the negative electrode. De la Rive asks whether this can be attributed to the static electricity with which the molecules are charged, and which augments their inherent repulsion? The luminous aurora which surrounds the negative electrode proves that at equal tensions the

negative electricity issues more readily than the positive from the metallic electrode; therefore the portion of the surrounding medium nearest the negative electrode should be more charged with static (negative) electricity than the part of the rarefied gas near to the positive electrode. It is not, therefore, surprising that the molecular repulsion of the gas and its consequent rarefaction are greater in the neighbourhood of the former electrode. Why, however, negative electricity diffuses itself more readily than positive, under like conditions, is still a mystery.

The next section of M. De la Rive's memoir deals with the practical phenomena presented by the stratification, which he has studied in a new manner in order more effectually to observe the resistance to the transmission of the electricity in the different portions of the tube. He uses two small discs of platinum 7 millimètres in diameter, and each fixed by a point in their circumference to the extremity of a platinum wire in a glass tube, in such a manner that the discs are preserved in a state of parallelism at a distance of 3 centimètres. The two discs are firmly held together and perfectly insulated, except as far as regards the wires soldered to their circumference, the extremities of which can be placed one by one in communication with that of the galvanometer. The apparatus is so arranged that the two discs of platinum can be introduced in the stratification, either cutting it transversely or with their centres situated in its axis. They can thus be introduced in any part of the stratification, take up the intensity of that part, which will be smaller as the conductibility of the interval from the derivation of the current is greater, and thus measure by the deflection of the needle of the galvanometer the exact intensity of the part examined.

The following table will conveniently show the result of an experiment of this kind in nitrogen and atmospheric air:—

INTENSITY OF DERIVED CURRENT.

Pressure.	Discs near Positive Electrode.	Discs near Negative Electrode.
6 millimètres	70°	18°
4 „	40	8
2 „	18	3

and in hydrogen—

INTENSITY OF DERIVED CURRENT.

Pressure.	Discs near Positive Electrode.	Discs near Negative Electrode.
15 millimètres	90°	90°
6 „	82	65
4 „	52	2

It thus appears that the intensity of the derived current diminishes with the pressure; but the diminution of the derived current, and consequently of the resistance, is much greater when the discs are placed in the darker portion near the negative electrode.

M. De la Rive, while dealing with this subject, points out the enormous luminous and calorific power of electricity, by means of which hydrogen reduced to a pressure of 1·5 millimètres becomes not only luminous, but heated to such a degree by the passage of electricity, that in two minutes the temperature of a thermometer with a cylindrical reservoir is raised some three degrees. An analogy is also insisted upon between this finely-divided matter and that of comets.

The last part of this memoir, which our space compels us to analyse so imperfectly, deals with the influence of magnetism on the various stratificative phenomena dealt with in the other parts of the paper.

M. De la Rive's researches on these subjects comprise two series of experiments: the first in which the electro-magnet is placed outside the rarefied gas; the second in which the soft-iron magnet is situated in the rarefied gas itself. The experiments of the latter class have been made by the apparatus recently described in these pages as having been exhibited at the Royal Society soirée. Many elaborate series of experiments made by both apparatus are described; all the phenomena observed show, in a very striking manner, as M. De la Rive points out in conclusion, the molecular differences which the various media, even at an extreme degree of rarefaction, present among themselves. Thus, in hydrogen, although this gas is a very good conductor, the electric jets can only obey with great difficulty the action of the magnet, possibly on account of the very small density of the gas.

In air and nitrogen the matter is very different, and more altered still when the gases are mixed with aqueous vapour. The singular property which the jet has of subdividing itself into several small distinct ones, instead of disappearing under the magnetic influence when the medium contains a greater or less quantity of vapour, would seem to indicate that there is more cohesion in the vapour than in the gases properly so called, if, indeed, one can employ the term cohesion when the particles are so incoherent. There remains, however, a question whether this division into jets be an optical illusion due to the very rapid succession of jets not simultaneously issuing from different points.

M. De la Rive concludes this admirable and very suggestive addition to our electrical knowledge with the following remarks:— "It is evident that the study of the stratification of the electric spark, and of the action of the magnet on the discharges in different gaseous media, shows in these media differences which can only arise from a difference in their molecular constitution. Density particularly would seem to have a great influence on this class of phenomena, since we see hydrogen manifesting them in such a feeble degree, while aqueous vapour, and especially the vapours of alcohol and ether, presents us with them in such a remarkable manner. The constitution of elastic fluids, which more or less resists the transmission of electricity, doubtless plays a part. It is not, therefore, impossible that we shall be able, in a more detailed and profound study of these phenomena, and especially of those which relate to the action of the magnet, to find a means of obtaining some new facts relating to the physical properties of bodies, and the manner in which electricity itself is propagated in them."

ABRIDGMENTS OF SPECIFICATIONS RELATING TO ELECTRICITY AND MAGNETISM, THEIR GENERATION AND APPLICATION.

III.

A.D. 1786.—Cassini, in 1786, discovered the annual periodical variation of the magnetic needle. (See Sir W. Snow Harris' *Rudimentary Magnetism*, Part III., p. 87.)

A.D. 1786, 1787.—Coulomb, in 1786 and 1787, established the law that magnetic force was really in the inverse duplicate ratio of the distances, by his Balance of Torsion, and by the method of oscillations. (See *Encyclopædia Metropolitana*, Vol. III., art. Magnetism, pp. 742, 743; also Sir W. Snow Harris' *Rudimentary Magnetism*, Part III., pp. 33-38; also De la Rive's *Treatise on Electricity*, Vol. I., pp. 180-183, and 533-542.)

A.D. 1792.—The Rev. A. Bennet, F.R.S., in 1792, used a magnetic needle, suspended by a spider's thread, as a magnetometer. (See *Philosophical Transactions*, 1792, p. 86; also Sir W. Snow Harris' *Rudimentary Magnetism*, Parts I. and II., pp. 105, 106.)

A.D. 1802.—Coulomb, in 1802, endeavoured to determine the question of a universal magnetism, and found all bodies that were tried finally settle in the direction of the straight line joining the poles, the needles of the various substances being suspended between opposite poles and in the same straight line with the magnet's axes. (See Sir W. Snow Harris' *Rudimentary Magnetism*, Parts I. and II., p. 56.)

A.D. 1804.—Messrs. Gay Lussac and Biot, in the year 1804, "undertook, at the desire of the French Government, an aerostatic voyage, expressly for the purpose of ascertaining whether the magnetic force experiences any perceptible diminution at considerable elevations above the surface of the earth." The result of their experiments was that the magnetic force experiences no appreciable diminution at a height of 13,124 feet above the surface of the earth. In this case the effect of the diminution of temperature on the needle was not taken into account. (See *Library of Useful Knowledge*, Magnetism, p. 89.)

A.D. 1806, 1807.—Humbolt, in 1806 and 1807, observed magnetic storms at Berlin. (See Sir W. Snow Harris' *Rudimentary Magnetism* Part III., p. 103.)

A.D. 1809.—Professor Krafft, of St. Petersburg, in 1809, propounded the following law of terrestrial magnetism:—"If we suppose a circle circumscribed about the earth, having the two extremities of the magnetic axis for its poles, and if we consider this circle as a magnetic equator, the tangent of the dip of the needle, in any magnetic latitude, will be equal to double the tangent of this latitude." (See *Encyclopædia Britannica*, 8th edition, art. Magnetism, p. 7.)

A.D. 1813.—Colonel Beaufoy employed a very perfect form of variation of compass. This arrangement is described in the "Annals of Philosophy" for August, 1813; it consists of a telescope to determine the true meridian by astronomical observation, underneath the axis of which is a magnetic needle whose position is

alterable so as to show the angular deviation of the needle from the true meridian. (See Sir W. Snow Harris' *Rudimentary Magnetism*, Parts I. and II., pp. 150-152; also *Encyclopædia Metropolitana*, Vol. III., art. Magnetism, pp. 766, 767.)

A.D. 1813.—Morichini, in 1813, magnetized a needle by means of the violet ray of the spectrum. (See *Library of Useful Knowledge*, Electro-magnetism, p. 97; also Sir W. Snow Harris' *Rudimentary Magnetism*, Parts I. and II., p. 69.)

A.D. 1817.—Mr. Westcott explained his magnetic guard for needle pointers before the Committee of Mechanics of the Society of Arts, on March 27, 1817. This instrument consisted of "a number of bar magnets, smeared with oil, placed in a frame behind the grindstone." (See *Transactions of the Society of Arts*, 1824, Vol. XLII., pp. 165, 166.)

A.D. 1817.—Professor Hansteen, of Christiana, in 1817, confirmed the law that magnetic force is inversely as the squares of the distances, by the action of the pole of a magnet upon a pivoted needle mounted as in the declination magnetometer. Professor Hansteen, in connection with M. Morlet, determined the position of the nodes of the terrestrial magnetic equator. (See Sir W. Snow Harris' *Rudimentary Magnetism*, Part. III., pp. 38, 39; also *Encyclopædia Britannica*, art. Magnetism, p. 57.)

A.D. 1817.—Professor Barlow, of Woolwich, commenced a series of experiments on the influence of spherical and other masses of iron on the compass needle, soon after the appearance of Professor Hansteen's work on the Magnetism of the Earth in 1817, and found the existence of a plane of no deviation of the needle at right angles to the direction of the dipping needle, and other laws of magnetic force. (See *Encyclopædia Metropolitana*, Vol. III., art. Magnetism, pp. 743 and 775; also Sir W. Snow Harris' *Rudimentary Magnetism*, Part III., pp. 69-76.)

A.D. 1818.—Mr. George Fisher, in 1818, found that the rate of going of chronometers is influenced by the proximity of a mass of iron. (See *Library of Useful Knowledge*, Magnetism, p. 68.)

A.D. 1820.—Sir David Brewster, in 1820, remarked the connection between the terrestrial magnetic poles and those of maximum cold. (See *Encyclopædia Britannica*, 8th edition, art. Magnetism, p. 11; also *Edinburgh Philosophical Transactions*, 1820.)

A.D. 1820.—Professor Barlow, in 1820, applied his correction plates to the "Leven," "Conway," and "Barracouta," to prevent local magnetic attraction. (See *Encyclopædia Metropolitana*, Vol. III., art. Magnetism, p. 799; also *Transactions of the Society of Arts*, 1821, Vol. XXXIX., pp. 76-100.)

A.D. 1821.—Captain Kater, in 1821, found that shear steel is capable of receiving the greatest magnetic force, and that the pierced rhombus is the best form for a compass needle. He found that the directive force depends on the mass of the needle when magnetized to saturation. The method of hardening the needle preferred by Captain Kater is to harden it entirely throughout, and then soften it in the middle. (See *Library of Useful Knowledge*, Magnetism, pp. 57, 58; also *Encyclopædia Britannica*, art. Magnetism, p. 77; also *Encyclopædia Metropolitana*, Vol. III., art. Magnetism pp. 754, 755, and 770-773.)

A.D. 1821.—Mr. J. H. Abraham, of Sheffield, 1821, invented a magnetic guard to protect persons employed in pointing needles and other branches of dry grinding. According to one arrangement, a frame of bar magnets surrounds the operator's mouth; another arrangement consists in placing bar magnets just above the needles whilst they are being pointed; in the arrangement for dry-grinding cutlery, &c., the magnets are placed radially or longitudinally (or both ways) inside a hood near the point of grinding. The large gold medal of the Society of Arts was awarded to Mr. Abraham for this invention. (See *Transactions of the Society of Arts*, 1823, Vol. XL., pp. 135-150.)

A.D. 1822.—Lieutenant Littlewort, R.N., in 1822, received the large silver medal of the the Society of Arts for an improved ship's compass. This compass may be used either as a hanging compass, a steering compass, or an azimuth compass; for the latter purpose the suspending handle may be inverted and made to support the compass in a box (the said box being moveable about a centre), the card has a graduated silver circle, and moveable sights and a stop are annexed. (See *Transactions of the Society of Arts*, 1823, Vol. XL., pp. 70-72.)

A.D. 1823.—Professor Barlow, in 1823, proposed to render the diurnal variation of the needle more distinctly marked, by deflecting it from the magnetic meridian by means of a permanent magnet. (See Sir W. Snow Harris' *Rudimentary Magnetism*, Parts I. and II., pp. 152, 153.)

A.D. 1824.—Arago, in 1824, found that various substances (metallic substances more especially) have an influence on the oscillations of the magnetic needle. (See *Library of Useful Knowledge*, Magnetism, p. 91.)

A.D. 1825.—Mary Somerville, in the summer of 1825, magnetized a sewing needle by exposing one half to the violet rays of the spectrum; in two hours the exposed end had the properties of a north pole. (See *Library of Useful Knowledge*, Electro-magnetism, p. 97.)

A.D. 1825.—Mr. Christie, about 1825, proved experimentally that heat diminishes magnetic force. (See *Library of Useful Knowledge*, Magnetism, p. 13.)

A.D. 1829.—M. Kupffer, in 1829, observed the diminution of the magnetic force with the height, at the summit of Mount Elbrouz in the Caucasus. (See De la Rive's *Treatise on Electricity*, Vol. III., p. 242; also *Library of Useful Knowledge*, Magnetism, p. 89.)

A.D. 1829.—De la Rive, in 1829, observed a diminution of inclination of the needle at the Hospice of the Great St. Bernard. (See De la Rive's *Treatise on Electricity*, Vol. III., p. 242.)

A.D. 1830.—Haldat, in 1830, produced magnetism by the friction of hard bodies. He also proved that magnetic figures might be formed by tracing them upon a steel plate with a magnetic pole; they are rendered visible by sifting filings of steel upon them. (See *Encyclopædia Britannica*, 8th edition, art. Magnetism, pp. 13, 14.)

A.D. 1830.—Quetlet, in 1830, made experiments relating to "the successive degrees of magnetic force which a steel needle receives during the multiple frictions which are employed to magnetize it." (See *Encyclopædia Britannica*, 8th edition, art, Magnetism, p. 14.)

A.D. 1831.—Dr. Roget, in 1831, published an account of a mechanical instrument for generating magnetic curves. (See *Journal of the Royal Institution*, February, 1831; also Leslie's *Geometrical Analysis*, p. 399; also *Library of Useful Knowledge*, Magnetism, pp. 19-22; also Sir W. Snow Harris' *Rudimentary Magnetism*, Part III., pp. 66-69; also *Encyclopædia Metropolitana*, Vol. III., art. Magnetism, pp. 793-795.)

A.D 1831.—Sir W. Snow Harris, in 1831, invented a mariners' compass consisting of the following parts:—A light bar-edged magnet with a central cap, the said magnet being hardened and tempered throughout. Small sliders of silver compensate for the dip, the magnet having been poised horizontally before magnetization. This card consists of painted talc, and has a cross-bar of brass, with adjustable sliders. The point of suspension proceeds from a double curved bar fixed as a diameter to a dense ring of copper, so as to take advantage of the ring's "magneto-electrical" restraining force in preventing the oscillations of the compass card. (See Sir W. Snow Harris' *Rudimentary Magnetism*, Part III., p. 149.)

A.D. 1831.—Sir W. Snow Harris first employed the bifilar suspension for needle magnetometers in 1831. (See *British Association Reports*, Vol. IV., p. 17; also Sir W. Snow Harris' *Rudimentary Magnetism*, Parts I. and II., p. 120.)

A.D. 1831.—Sir W. Snow Harris invented his hydrostatic magnetometer about the year 1831. (See Sir W. Snow Harris' *Rudimentary Magnetism*, Parts I. and II., pp. 35, 115.)

A.D. 1831.—Sir W. Snow Harris used a modification of the scale-beam magnetometer about the year 1831. (See Sir W. Snow Harris' *Rudimentary Magnetism*, Parts I. and II., p. 35.)

A.D. 1831.—Professor Barlow, in 1831, coiled a hollow wooden globe with copper wire placed in the parallels of latitude. On an electric current being transmitted through this coil, "a magnetic needle suspended above the globe, and neutralized from the influence of the earth's magnetism, exhibited all the phenomena of the dipping and variation needles, according to its positions with regard to the wooden globe." It is inferred from this experiment that the earth may "be considered as only transiently magnetic by induction, and not a real magnet." (See *Encyclopædia Britannica*, art. Magnetism, p. 64, 65; also Sir W. Snow Harris' *Rudimentary Magnetism*, Part III., pp. 120-122; also Mary Somerville's *Connexion of the Physical Sciences*, p. 366.)

A.D. 1832.—Pouillet described the astatic magnetic needle in his "Elements of Physique," Paris, 1832. (See *Encyclopædia Britannica*, 8th edition, art. Magnetism, p. 90.)

A.D. 1832.—Captain Milne, R.N., in 1832, proposed a corrected compass card to obviate the errors incidental to local attraction. (See Sir W. Snow Harris' *Rudimentary Magnetism*, Part III., p. 171.)

A.D. 1832.—The Rev. Dr. Scoresby, in 1832, measured distances by the action of a magnet on the compass needle. (See Sir W. Snow Harris' *Rudimentary Magnetism*, Part III., p. 185; also *Edinburgh New Philosophical Journal*, April, 1832.)

A.D. 1835.—Mr. Fox, in 1835, measured the variation, dip, and magnetic intensity of the magnetic needle by means of his "dipping needle deflector." (See *Encyclopædia Britannica*, 8th edition, art. Magnetism, pp. 87-89.)

A.D. 1836.—Gauss, in 1836 and 1837, employed the unifilar and bifilar magnetometers in connection with a divided scale and theodolite, to observe the variations of terrestrial magnetism. (See De la Rive's *Treatise on Electricity*, Vol. III., pp. 212-217, also p. 308.)

A.D. 1838.—Professor Airy, in 1838, proposed to correct ships' compasses, and to obviate the effects of local attraction upon them, by means of magnets. (See Sir W. Snow Harris' *Rudimentary Magnetism*, Part III., pp. 174-177; also *Transactions of the Royal Society*, 1839.)

A.D. 1838-1839-1840.—The "Admiralty compass," resulting from an inquiry instituted 1838-40, consists of four of Scoresby's compound magnetic bars, card of mica, copper compass bowl, and spare cards and electro-gilt steel pivots. (See Sir W. Snow Harris' *Rudimentary Magnetism*, Part III., pp. 145, 106.)

A.D. 1839, 1840.—Dr. Kreil, in 1839 and 1840, at Prague, made some noteworthy observations on the influence of the moon on the magnetic elements of the earth. (See *Encyclopædia Britannica*, 8th edition, art. Magnetism, p. 19.)

A.D. 1842.—Dr. Lloyd, in 1842, proposed an indirect method of measuring the inclination of the compass and its changes. (See *Encyclopædia Britannica*, 8th edition, art. Magnetism, p. 87.)

A.D. 1842.—M. Plantamour, having observed the variations of the magnetic elements at Geneva during the years 1842, 1843, points out that the position of the moon with respect to the earth is not without influence upon the movements of the magnetized needle. (See De la Rive's *Treatise on Electricity*, Vol. III., pp. 261, 262.)

A.D. 1844.—Baron Reichenbach, in 1844, made researches respecting the action of the magnet upon the human frame, more especially upon certain people denominated "sensitives." These people, in an absolutely dark room, uniformly perceived luminous emanations of various tints at different parts of the magnet. The luminosity of the magnetic emanation was confirmed by the fact of its image being able to be fixed on a daguerreotype plate. Other effects of magnets on the human frame are described. (See Reichenbach's *Researches on Magnetism, Electricity, Heat, Light, Crystallization, and Chemical Attraction in their relation to Vital Force*. Translated and edited by Dr. Gregory, London, 1846.)

A.D. 1845.—Faraday, in 1845, discovered that when a ray of polarised light is made to pass through a piece of heavy glass (consisting of silico-borate of lead) placed near a magnetic pole, in such a manner that the lines of magnetic force shall pass through the glass in the direction of the ray, the ray rotates according to the following law:—"If a magnetic line of force be *going from* a north pole or *coming from* a south pole along the path of a polarized ray coming to the observer, it will rotate that ray to the right hand, or if such a line of force be coming from a north pole or going from a south pole, it will rotate such a ray to the *left hand*." (See *Philosophical Transactions*, 1846, Vol. I., p. 1; also Gmelin's *Handbook of Chemistry*, Vol. I., pp. 168, 169; also Sir W. Snow Harris' *Rudimentary Magnetism*, Parts I. and II., pp. 71-73.)

A.D. 1846.—Mr. Wartmann, about the year 1846, "announced that a piece of rock salt, placed in the route of polarized rays of heat, determines the rotation of the plane of polarization, if a powerful electro-magnet is made to act upon it." (See De la Rive's *Treatise on Electricity*, Vol I., p. 525.)

A.D. 1846.—Faraday, in 1846, propounded the laws of diamagnetism. According to this discovery, certain bodies are found to place themselves at right angles to the straight line joining the poles of a magnet, when freely suspended so as to be capable of motion in all directions round a centre; this position is called "equatorial," in contradistinction to that assumed by magnetic bodies, such as iron, which are said to take up an "axial" direction when under magnetic influence. In these investigations the most powerful magnetic bodies were found to be iron, nickel, cobalt, manganese, and chromium; the most powerful diamagnetic bodies were found to be bismuth, phosphorus, antimony, heavy glass, and zinc. (See *Athenæum*, January 31, 1846; *Practical Mechanic and Engineers' Magazine*, February, 1846, pp. 117, 118.)

A.D. 1847.—Professor Bancalari, in 1847, published his researches on the diamagnetism of flames and gases. (See Noad's *Manual of Electricity*, pp. 842-844.)

A.D. 1847.—Brooke, in 1847, invented the photographic system of registering the variations of terrestrial magnetism, and subsequently put it into practice at Greenwich. (See De la Rive's *Treatise on Electricity*, Vol. III., pp. 217-222, also p. 308.)

A.D. 1848.—Faraday, in 1848, discovered magneto-crystalline force. The line in which this directive force is exerted is called the "magne-crystalline line"; this line is found to have relation to the crystallization and optic axes of bodies in which its presence is manifested. MM. Plucker and Beer also made experiments showing the nature of this force. (See *Athenæum*, No. 1103, p. 1266; also Gmelin's *Handbook of Chemistry*, Vol I., pp. 514-519; also De la Rive's *Treatise on Electricity*, Vol. I., pp. 482-497.)

A.D. 1850.—MM. Tyndall and Knoblauch, in 1850, succeeded in showing the relation of the magneto-crystalline force, or manifestation of force, to magnetic and diamagnetic force. They found "that the magnetic properties of the optical axis are connected with a general principle, namely, that when the molecular constitution of any body is such that the particles of which it is formed are nearer to each other, according to a certain direction, than in the rest of the mass, this direction, all other circumstances remaining the same, is that in which the forces which are acting upon the body manifest their action with the greatest energy; so that the line which represents this direction places itself axially or equatorially, according as the substance is magnetic or diamagnetic." (See *Philosophical Transactions*, 1850, Vol. XXXVII., p. 1; also De la Rive's *Treatise on Electricity*, Vol. I., pp. 490-497.)

EXPERIMENTAL ELECTRO-PLATING.

(By a Student.)

Electro-plating is based on exactly the same principles as electro-typing in copper; but, on account of the greater expense of the materials used, a mould is seldom, if ever, copied in solid silver, as is the case with copper; but, in order to give it the appearance of being executed in silver, a thin deposit of that metal is produced on its surface, by the process which we will now describe. The silver solutions may be prepared in either of the two following ways, we recommend the latter:—1. Dissolve any small silver coin, such as a sixpenny piece, in aquafortis (nitric acid); the solution will have a blueish tinge, owing to the copper contained in the coin. Now add to this solution another solution of common salt, in water; this will throw down a precipitate of chloride of silver. When it has settled at the bottom of the glass, pour off the solution from above it, and fill the glass with water; let it again settle down, and then again pour off the water. This operation, which is called "washing the precipitate," must be repeated two or three times. Now make a solution of cyanide of potassium, of the strength of about half-an-ounce of that substance to one pint of water, and throw into it the white precipitate; in a few minutes it will all be dissolved, and then the solution is ready for use. 2. Dissolve an ounce of the crystals of nitrate of silver in about two ounces of pure distilled water, and add to it a solution of caustic potash until no more precipitate is thrown down; wash this precipitate as directed in the first instance, and then dissolve it in a similar solution of cyanide; this solution being carefully prepared, the rest of the arrangements are very easily set up. On account of the costly nature of the solutions used, it is better to put them for use into glass vessels. Instead of the wooden decomposing cell recommended for the copper process, a large tumbler, or a finger glass, are among the best things which the student can obtain for the purpose, without going to any great expense about it. A couple of brass rods can be laid over it.

The same battery may be used for the plating as is used for the copper process, and the power may be about the same, or rather less. The student will probably find it more convenient to silver his moulds one at a time, in which case a piece of wire may be attached to the back of one of them, by twisting round any prominent part near the edge, and the other end of the same wire may be twisted round the top of the zinc plate of the battery. A piece of silver foil, of about the same size as the mould to be silvered, is now to be connected, in a similar manner, with the copper plate of the battery. The silver plate and the mould are now to be immersed in the silver solution; in about ten minutes or a quarter of an hour the mould will be covered with a deposit of sufficient thickness to render it quite durable; the mould may now be removed from the solution, washed, and dried. It will, however, most likely be very dull-looking; it will, therefore, want cleaning, which may be done by any of the modes used by the household to clean the "plate." It is an operation requiring much time and care to get a really good polish on one of these electro-plate

moulds; however, it may be done by that patience and perseverance which overcomes all difficulties. Practically, where this electro-plating is carried on on a large scale, the goods, when removed from the "bath," or decomposing cell, are burnished with steel burnishers.

In order to be quite successful in plating, the following circumstances must be attended to:—1. The room should not be of a temperature much lower than 60°. 2. The silver plate and the mould should be immersed in the solution and taken from it as nearly as possible at the same time. 3. The copper mould must be kept *quite* clean. In order to obtain it in this state it must be dipped in a mixture of nitric and sulphuric acids, very much diluted with water, and then rubbed with a soft cloth.* When it is quite clean it is best to throw into it a tumbler of water, until the time comes to put it into the solution in the cell.

THE PERSIAN GULF TELEGRAPH.

(*Continued from page* 57.)

Reverting to our subject, the paying out of the Kirkham's cable proceeded smoothly at the rate of about five knots, until the fore tank was nearly empty. The anxious time for the engineers then arrived, the change from hold to hold would soon have to take place. The bight of the cable had to be carried up from the bottom of the hold, through the rings, and then through a narrow passage cut in the centre of the house on deck, and thence along the bridge, until it took up its new "lead" to the after tank. If the ship had the least bit too much way on her the bight would run itself up and along aft too fast for the men to handle it, and it would probably foul some projecting iron, or possibly jump itself into a kink. It was night; the first change of hold to be dealt with, and the worst, as it was from the fore to the after tank, so that the bight had to run nearly the whole length of the ship. Besides this, to avoid cutting some of the Kirkham's beams, and to dispense with the removal of the permanent galley, only a very narrow well through the galley had been built.

When there were only a few flakes of cable left in the fore hold an experiment was made as to the time the ship would take to lose her way when the motive power was taken off her, or rather as to the length of cable that would be payed out between the stopping of the Zenobia's engines and the moment when the Kirkham lost her way.

The Zenobia was eased and stopped, and the number of turns round the hold noted that passed out before the cable ceased to pay itself out. The paying out then proceeded until it was nearly time for the real change. As the time approached the watch below were called, and took their stations in the after tank, and on the bridge. Trustworthy and old hands were stationed to knock the pins at the proper instant out of the blocks in the loops of the rings previously described, to open the hawse pipe below the quadrant, and to hand the bight up to the bridge, an operation that requires some skill and experience.

Sir C. Bright took his station on the forecastle, to superintend the signalling to the Zenobia; Mr. Webb, on the lower deck, gave notice when it was necessary to ease and stop the ship, and gave orders as to the releasing or application of the brakes, and superintended the change generally; while Mr. Alexander took charge of the brakes themselves. All being ready, the Zenobia was eased and then stopped, just when it was considered, according to the previous experiment, the cable would run itself out of the fore hold by the time the ship had stopped; the brakes were at the same time released entirely. Gradually the cable swept round the hold slower and slower, then, stopping for a moment, would start into motion again, and surge out several turns round, until when, after about twenty minutes, the cable stopped entirely, there was literally only half a turn left round the hold, so well had the time required to stop been estimated.

Not a word had been spoken during this time, and as the last movement of the cable ceased the silence was complete, and was then broken only by the order to "put the brakes hard down, knock out the pins in the loops, open the hawse, and hand the bight up, and haul down in the after hold," which was executed with great regularity and precision, the bight being carefully handed up the hatch by an experienced foreman named Jackson, and along the bridge by another named Bishop. At the same time the men in the after tank hauled down the slack cable until, when the bight was thus all drawn down into the after hold, the cable lay fair in the fairleaders from the after hold to the brake. The brakes were then eased up, and the signal made to the Zenobia to "go on" at 5.35 a.m. of the 5th. Thus the first change of hold ever executed in a ship under tow had been successfully accomplished.

The paying out then proceeded as before, with great regularity. At 7 p.m. of the 5th a long abstract of political news, just received at Bombay by the English mail, was received from the shore, through the cable, on board the Kirkham, and this was telegraphed on to the Zenobia, by means of the lamp telegraph, with great rapidity. About 7.30 p.m. the change from the after to the main hold was executed, and owing to the size of the main hold and its more circular form, and the design of the rings, cones, &c., being unfettered by any consideration of beams, the arrangements here were so perfect that the cable swept round with the most perfect regularity. The speed was increased to the greatest speed the Zenobia could attain, which at times reached nearly six knots.

At 10.40 of the 6th the cable was nearly all payed out of the Kirkham, and she was anchored, when about half a mile was left in the hold, off Ras Mundarony.

The Semiramis, with the Marian Moore in tow, soon hove in sight, and the signal was made from the Marian Moore "anchor on our starboard bow," which was accordingly done.

The cable in the hold was then hauled up and coiled down on deck, and the end passed out of the stern sheave, and hauled by a hawser on board the Marian Moore; the bight of the cable was then carefully lowered over the stern of the Kirkham into a boat, and when all the slack had been hauled in on board the Marian Moore, the bight was let go from the boat at about 4 p.m., thus freeing the cable finally from the Kirkham.

During the rest of the day some of the gear, stores, and men were transhipped to the Marian Moore. The next day, the 7th, the transhipment proceeded, and the splice having been made during the night, at about 3 p.m. the Zenobia took the Marian Moore in tow, and at 4 p.m. both ships weighed, and paying out was again resumed. At 4.25 a.m. of the 8th the change from the fore to the after hold of the Marian Moore was effected, and at 9.45 a.m. the ship was anchored, and the rest of the squadron anchored off Ras Jask, where it was arranged that the ships should stop till 6 p.m., so that the opposite coast and Malcolm's Inlet might be made at daylight the following day. Towards the afternoon the weather looked threatening, but nevertheless, a start was made at 6.30 p.m., and the weather resuming its favourable aspect, the paying out proceeded as before. At 11.10 p.m. the change from the after to the main tank occurred, and was executed with equal success to the previous changes, all of which, it will be remembered, occurred during dark.

About 9 a.m. Malcolm's Inlet was entered, and at 3.40 p.m. the Marian Moore anchored in twenty-eight fathoms, having about six miles left in the hold.

Preparations were then made by Colonel Stewart for erecting a temporary camp and station on the isthmus that separates Malcolm's Inlet from Elphinstone Inlet. The place originally proposed for the station was Kasab, a village on the coast, about nine miles to the westward of the isthmus, but as no preparations for a station there had been commenced, it was determined to erect a temporary station on the isthmus itself for the present.

The isthmus itself is rocky, and steep, and high, and it required considerable labour and energy to drag all the necessary material of stores, provisions, and water for a station to the selected site. By the 13th matters were, however, sufficiently advanced to permit the landing of the end to be proceeded with, and this was accordingly accomplished by about noon, amidst salutes from the Zenobia, Coromandel, and Marian Moore. The water was deep for such an operation, and special precaution had to be taken. The usual hemp stoppers in the boats were replaced by two messengers rove through blocks in the bows of the sternmost boat, or "stopper boat." One of these was made fast to the cable, and then eased away by a turn round the tharnt, until the hitch was close aft, when the other messenger was bent on, and the first cast off, overhauled again in time to be made fast again by the time the hitch of the first reached aft. Thus all danger of a "run" was avoided.

After the cable had been properly entrenched ashore it was tested electrically, and found perfect, and the engineer's duty of laying the first section thus satisfactorily accomplished.

On the evening of the 14th the Marian Moore, with Messrs. Webb, Laws, and the rest of Sir C. Bright's staff, left in tow of the Zenobia for Bombay, in order to see the Assaye and Tweed, which ships had arrived at Bombay, finally prepared before they were brought up the Gulf.

The Marian Moore arrived at Bombay on the evening of the 21st, and the next day she was taken alongside the Tweed, and all the cable that remained in her transferred to the Tweed. All the buoys, ropes, chain anchors, and gear, together with the men, amounting to about fifty-four in all, were then transferred to the Tweed, and finally all the cabin furniture was transhipped; and on the 26th the engineering and electrical staff shifted over to the Tweed. All the preparations of the machinery and holds in the Tweed and Assaye were finally completed by the 29th, and on the 1st of March the Tweed, in tow of the Zenobia, and the Assaye, in tow of the Semiramis, started for the Gulf.

On the 11th of March the Tweed brought up off Kasab, and on the 13th the Zenobia took her in tow into Elphinstone Inlet, and anchored her near a little island where the station had been established by Colonel Stewart in place of the isthmus, when it was found the native Arabs were rather troublesome, the link between the island and the isthmus having been supplied by a piece of india-rubber covered cable, laid by Sir C. Bright. This piece of cable was found defective, and it became necessary to replace it by a piece of the ordinary Persian Gulf cable, and, as a double precaution, two lengths of these were laid on the 14th and 15th.

The Semiramis and the Assaye had arrived on the evening of the 13th, and left to coal at Basidore on the 18th. On the 18th the end from the Tweed was landed on the island, and on the evening at 5.30 of the same date the second section was commenced, the Zenobia being still the towing vessel.

The paying out proceeded well all that night. On the evening of the 19th, however, the wind, which was from the westward, freshened, and retarded the progress so that the paying out was reduced at one time to 2½ knots per hour.

At night the wind dropped, and the paying out proceeded favourably. On the 20th two changes of holds were executed with the same regularity and success as before.

On the 21st, at 8 p.m., nearly all the cable in the Tweed was expended, and the vessel was brought up, being distant from Bushire about thirty-two miles. The Coromandel had parted company with the paying-out ships off Basidore to fetch on the Assaye, in order to avoid the detention which would have taken place had that vessel waited for the Semiramis to coal. About midnight the Coromandel arrived with the Assaye in tow. The next day the end was passed from the Tweed to the Assaye, and the shifting of gear, men, and staff commenced while the splice was being proceeded with.

At 5 a.m. the Amberwitch, the little steamer that is fitted up for reparing the cable, commanded by Lieutenant Stiffe, joined the expedition.

At 2 p.m. of the 23rd paying out was again commenced from the Assaye, and at 9.15 a.m. of the same date the Assaye was anchored off the landing-place near Bushire, Lieutenant Stiffe, in the Amberwitch, having piloted the vessel to her anchorage, which was nearly three miles distant from the shore.

On the 24th half a mile of cable was coiled into the paddle-box boats of the Zenobia, and two and a half into the Amberwitch; and at 5 p.m. the bight was let go from the Assaye, and the Amberwitch payed out the cable towards the shore, and anchored about half a mile from the beach. The remainder in the paddle-box boats was then payed out, and the end landed about 8 p.m., almost in total darkness. The cable was then led up the cliff, and along a trench, to a small camp prepared for the reception of the end, about six miles to the eastward of the town of Bushire. Thus ended the laying of the Mussendum and Bushire section.

The next day Lieutenant Stiffe was despatched in the Victoria, Lieutenant Arnot, to lay down buoys on the proposed route of the cable near Fau, where the Gulf begins to get shallow, and consequently required the selection of the deepest water that could be procured for the more perfect safety of the cable.

On the 25th the Assaye was towed by the Amberwitch to a position west of her previous anchorage, so that the next section might not overlay the part just laid.

The necessary length of cable was then payed into the Amberwitch and paddle-box boats, and at 5 p.m. again the Amberwitch payed out towards the shore, and anchored close in, and the first end of the Bushire and Fau section was landed at night by lamp-light.

On the 26th, 2.50 p.m., the paying out was once more commenced, the Coromandel being a-head, the Zenobia towing the Assaye, and the Amberwitch following.

On the morning of the 27th (Easter Sunday) the Victoria was sighted in position, and the various buoys laid by Lieutenant Stiffe were passed in succession, and at about 7 p.m. the Assaye, being in about four fathoms, anchored, thus ending all the paying out that was required from the large sailing ships between Gwador and Fau.

A grand lighting up of the Assaye with blue lights on every yard-arm and mast-head, and discharges of rockets, celebrated this stage in affairs. The next morning the difficulties yet to be overcome became very apparent. No land was visible with the naked eye, and with the glass only was it possible to discern a faint broken grey line which represented the shore, where yet had to be taken the cable. This shore was about nine miles distant, the bottom shoaling gradually the whole way.

On the 28th Colonel Stewart, Sir C. Bright, Captain Bradshaw, and Colonel Goldsmid started in the Coromandel and Victoria for Fau, to reconnoitre, and make arrangements for a portion of the land line, four miles in length, which was necessary to join Fau, a village on the Shat-El-Arab, to the place where the cable was to be landed.

At noon of the same day Mr. J. C. Laws, the electrician, reported "no continuity" between the Assaye and Bushire, and the fault 92.5 N. miles distant from end on board Assaye, the insulation being at the same time perfect.

Mr. F. C. Webb, in the absence of Colonel Stewart and Sir C. Bright, then immediately began to take steps for the repair of the line, and as it was no longer of any use to keep the cable hanging over the stern, requiring, as it did, very careful and arduous evolutions, with a kedge anchor on the swinging of the ship at each change of tide (which ran here about four knots), the cable was cut and buoyed over the stern, and the ship allowed to swing freely to her anchor. The next morning (29th) at daylight the end was picked up, and the Assaye moved half a mile away from it, and the end then permanently buoyed with two buoys. The Amberwitch was then hung to the Assaye, and prepared to take cable from the latter vessel.

In the meantime Colonel Stewart and Sir C. Bright having returned and approved of all that had been done, the Zenobia was despatched to take Messrs. Laws and Lambert to Bushire, to corroborate their tests from that end of the section.

At 10 p.m. of the 29th hauling in from the Assaye, by means of the steam "picking-up" machinery in the Amberwitch, was commenced, and continued through the night without intermission, and at 11 a.m. of the 30th 21·5 miles of cable had been transhipped, which was considered ample for any repairs that might be required.

A great deal of spare machinery had then to be shifted from the Amberwitch, and afterwards the men, stores, and gear had to be shifted to the Amberwitch. This was all accomplished by midnight, in spite of a very dark night and very heavy tideway, and at 1 a.m. of the 31st Mr. F. C. Webb, at whose disposal the Amberwitch had been placed by Colonel Stewart for the operation of repairing the line, accompanied by Mr. J. Woods, took passage in that vessel, and started for the locality of the fault.

At 4 p.m. of the 31st the Zenobia was met returning from Bushire, and Mr. Laws and his assistant, Mr. Lambert, took passage in the Amberwitch, having tested from Bushire, and found that the tests taken from both ends made the fault at 93·4 from the end in the Assaye, or a difference of only 0·9 from the single test. The Amberwitch was then run on until the Island of Karrick was approached sufficiently for the ship's position to be carefully fixed by angles to the objects on shore.

The distance and course out to the position of the fault was then run, and a buoy, having a lantern on it, moored at the spot, and dredging for the cable commenced at about 11 p.m. The cable was hooked at the second dredge, and hove up by the steam machines and cut at 4 a.m. of the 1st of April. The two ends were then tested, and the fault found to lay towards Fau, but quite close to. The end of the part leading to Bushire was then buoyed and let go, and the cable wound in towards Fau. When 2·46 N.M. were in the cable was cut, and the fault found to be in the piece thus cut off. The new cable in the hold was then attempted to be joined on, but it was found that a difficulty, once or twice before experienced on other cables, here interfered with the joining of the gutta-percha. As soon as the soft warm gutta-percha was applied to the joint the percha bubbled up, and thus prevented a perfect joint, showing that air was contained in the cable between the gutta-percha and the copper. About a third of a mile more cable was then hove in, and a second joint attempted, and no difficulty experienced. The splice was then made, and the new cable payed out towards the buoy on the Bushire end; but as it was night, and impossible to see the buoy, the cable was payed out until it was known that the two ends must overlap at least a quarter of a mile when the cable was cut and buoyed. On the following morning (2nd of April) the buoy on the Fau end was picked up, and the cable wound in until abreast of the buoy on the Bushire end. This end was then weighed, and the two sections being tested and found perfect, the final joint and splice was begun, and let go at about 3 p.m. The flag buoys were then picked up, and the ship started to join the rest of the ships off Fau.

On the 3rd the Amberwitch approached the Coromandel with the signal flying, "damage is repaired," which was answered by the signal from the Coromandel, on board which ship Colonel Stewart was, "accept my best thanks."

The fault had, in the meantime, been reduced, and cut out of the portion of cable picked up, and found to be a clean fracture in the copper, which must, from its appearance, have existed for a considerable time. The ends must, however, always have remained in metallic contact, as their separation would, of course, have been detected (as it was) the moment it occurred. It would appear that even the strain required to lay the cable was not sufficient to separate them, since they were in perfect contact for twenty-four hours after they were submerged. As the cable cooled down to the lower temperature of the water at the bottom of the sea, the copper wire contracting caused the two ends to separate, thus causing the loss of continuity, without any loss of insulation, to take place twenty-four hours after the cable was laid—a very unusual circumstance.

With regard to the reason of the fracture, it must be observed—firstly, that this, in all solid conductors, is an old evil, caused by the wire becoming burnt, and thus rendered brittle by the flame impinging on it during the process of annealing. The compound segmental wire used for the first time on the Persian Gulf cable was at first open to this same danger, since it was annealed after all the segments were placed together, and the portions first manufactured were thus open to a certain extent, though in a less degree than a perfectly solid conductor, to this old danger.

As the work of manufacture proceeded several improvements in the mode of annealing were introduced, and it is believed that the latter portions manufactured are entirely free from this possible source of danger. It was in some of the very first portions of the cable manufactured that the fault in question occurred. As it was, the fault was rather a happy incident than otherwise, since it demonstrated the rapidity with which the cable could under proper management be repaired, proving at the same time the exactitude of the electrician's tests, the care with which the course of the cable had been plotted off by the surveyors, and the completeness of the fittings and machinery of the Amberwitch.

During the time that the Amberwitch was thus employed, four miles of cable had been taken round in the Comet steamer to the Shat-El-Arab, and landed at Fau, where, under the energetic superintendence of Lieutenant-Colonel Goldsmid and Commander Bradshaw, R.N., it was stretched across and entrenched in the low, flat, muddy ground from Fau to the place where it was intended the cable should be landed.

On the 4th the Amberwitch, taking all the boats that could be spared from the different ships, steamed towards the landing-place, but even she could only approach to within about three and a quarter miles of high-water mark; and owing to the absence of any objects ashore to take angles or bearings to, it was believed that this distance was nearly four and a half miles. At 7 p.m. she anchored, and all that night was devoted to coiling five miles of cable into two paddle-box boats and two barges. The next morning, the 5th, the landing of the end (perhaps one of the most curious cable landings ever effected) was commenced. A string of seven boats, looking like a kind of sea-serpent, started at slack water to pay out cable from the Amberwitch to the barely visible shore.

First came a gig towing a lifeboat, which, in its turn, towed a heavy cutter, to which hung a paddle-box boat full of cable; then another paddle-

box boat; then a barge full of cable; and, finally, another barge full of cable. Every boat, even those containing cable (except the last from which the cable was payed out) was manned with men pulling. As one boat was emptied of her cargo of cable she was removed and returned to the ship, and the next one began; and so slowly, but surely, the little fleet of boats, lessening in its number, gradually approached the shore, until at last, when two barges had been emptied and nearly the whole of a paddle-box boat, the whole grounded on the mud. The shore (if a waste of damp mud can be called shore) was still distant about three-quarters of a mile, and, from its extreme flatness, looked much further off still. After a hasty lunch in the boats, finding no help come from the shore, it was determined to attempt to drag the bight across the mud by the force in the boats; boots, trousers, coats, &c., were dispensed with, pocket-books and purses were left hastily in charge of the boat-keepers, and watches and pipes stuffed down between the neck and the neckcloth, and all then with a "hurrah" made a dash into the mud, each sinking nearly to the waist, and throwing themselves on their hands and knees to avoid sinking altogether, each separate plunge being followed by roars of laughter at the ludicrous appearance of his comrade in muddiness. On went the whole party, wallowing, crawling, sinking, and gasping like turtles, and every now and then turning round and sitting fairly in the mud to rest for a moment, or laugh at the violent contortions of some struggling individual in the rear. At last the somewhat solid ground was, to the great relief of all, reached. A storm was now brewing, the sky became suddenly overcast, and it came on to blow and thunder and lighten, and the change of temperature was so great that literally many were glad to sit down in the water with which the cable trench was filled in order to keep themselves warm. Dark, the flowing tide, and a flood of rain compelled the men to relinquish the bight, and make for the shore as fast as possible. Four miles of walk across hard and soft mud, briers, and stubble in a storm of thunder and lightning and rain completed the day's work, and brought the whole to the Coromandel and the Comet lying in the Shat-El-Arab, when a hearty dinner and roars of laughter over the day's work finished the day.

The next morning (the 6th) many were knocked-up and ill by the previous day's work in the sun, mud, and rain, &c. Sir C. Bright, Mr. Laws, and Mr. Webb, with about four or five men, alone gained the Amberwitch, and at 2.30 commenced paying out from her towards the end of the Bushire sections, buoyed near the Assaye in the Core Abdulahs; and passing the buoys on this end the cable in the Amberwitch was cut and buoyed. At slack water this end was picked up at the bows, and afterwards the buoy on the "sea end" (or end of the portion leading to Bushire); the two ends being on board, and both portions having been tested and found perfect, the final splice was made, and the bight let go at 2 a.m. of the 7th of April, thus completing the line of cable between Gwador and the head of the Gulf.

(*To be continued.*)

HALF-YEARLY MEETING OF THE TELEGRAPH TO INDIA COMPANY.

AN extraordinary general meeting of the shareholders of the Telegraph to India Company, for the purpose of declaring a dividend for the half-year ending 30th June last, was held at the offices of the company, Moorgate-street, City, on Friday afternoon, the 12th inst.

There was an average attendance of shareholders, and the following directors were present:—Sir Macdonald Stephenson (the chairman), who presided; Captain Peel; C. L. Gaussen, Esq.; and William Dent, Esq.

The business of the meeting was commenced by the chairman calling upon the secretary to read the advertisement by which the meeting was convened. That having been done by Mr. W. Mayo, secretary,

The CHAIRMAN said, there was no report to present to the proprietors, but they were convened in accordance with the Act, for their approval and sanction of the declaration of a dividend of 2½ per cent. for the half-year ending 30th June, free of income-tax. Their Egyptian line was in excellent working order, and it had yielded a considerable profit to the lessees. And in case the India and China messages should be withdrawn, there would be profit from the local sufficient to pay a dividend. They still had the Red Sea and El Arish concession; and if the Persian Gulf line was successful, they would have the Red Sea and El Arish line as an alternative line. But should the Persian Gulf line prove a failure, they would still have the Red Sea and El Arish line to make use of. He proposed that a dividend at the rate of 5 per cent. per annum be declared for the half-year ending 30th June, to be payable on and after the 15th August.

Mr. DENT seconded the motion, which was unanimously agreed to.

The meeting then broke up.

THE ATLANTIC TELEGRAPH.—By a telegram received through Mr. Reuter's agency from Newfoundland, we learn that Her Majesty's surveying steamer Margaretta, Captain J. Orlebar, R N., returned to Newfoundland on the 6th instant, with Mr. Cyrus W. Field. They have selected Heart's Content, Trinity Bay, as the place for the landing of the Atlantic cable. The harbour of Heart's Content is one of the very best in Newfoundland, and the Great Eastern can enter it with perfect safety at all states of the tide, and anchor within a quarter of a mile where the cable is to be landed.

CORRESPONDENCE.

HAWORTH'S SYSTEM OF TELEGRAPHY.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—On looking through your paper this week I observed three letters on Mr Haworth's patent for telegraphing without wires. I was at first in hopes that they contained some explanation of that system, but I was disappointed. The first and second are evidently from telegraphists, and show clearly enough their opinion on the subject. The third is concerned simply with my personal self. It is a longish homily, treating on modesty and kindred virtues, and my special want of them. I am very much obliged to "E. F. G." for his lessons in humility, and will strive to profit by them. I will take him as a pattern of humility, as he evidently wishes me to do; for I perceive he is "a numble individual." But I must plead some little matters of extenuation. If I have dealt in ridicule and sarcasm, as my Mentor says, upon the word of a penitent, I really did not mean it. One thing suggests another, you see. "The sympathetic snail telegraph" would come uppermost in my mind. I could not help it; therefore, my dear Mentor, be pleased to lay that to the charge of "Association of Ideas." However beneficial this homily may be to my morals, I am afraid that such personal matters will not much benefit the art of telegraphy, nor be of much interest to the general reader. I would suggest to my Mentor, if it be not presumptuous in me to do so, that if, instead of that fine-ish writing about "elements made our bond-slaves," "the womb of the future being big, &c. &c.," "chrysalis doctors and professors," and all that sort of thing, he had just taken in hand Mr. Haworth's specification, and shown me wherein I have made an error in that which I have professed to understand, and set down in my notice of it, namely, the diagram of the currents, and the application of the laws of conduction and induction, as established these thirty years, to the attempt at understanding any useful application of such currents, this would have been a benefit to me and to the general reader. Certainly this would be rather a dull matter-of-fact way of treating the thing, and, as I can see, my dear Mentor, quite beneath your genius; but I merely say that it would have been rather satisfactory to me than otherwise; yet, at the same time, I am duly alive to the merits of that exalted, sensational-style of composition, though I do not hope ever to be able to imitate it. My dear sir, what is this? You are a friend of Mr. Haworth's, you say. Let me transcribe this. "I confess Mr. Haworth's method is a riddle to me. I cannot understand it, and to attempt to get an insight into the *modus operandi* by means of the specification of his patent is like, to use a homely phrase, 'looking for a needle in a bundle of hay.'" Is not this an accusation of deception, nay, of untruthfulness? My dear sir, I am shocked! Has not Mr. Haworth, in his specification, given his word that he has fully described his invention, and how it is to be carried out. Moreover, the law demands this as a condition to his having a patent granted, and that it be in such wise that an ordinary person can understand it. I see, my dear Mentor, that either you estimate your intelligence quite below the average, or as low even as you estimate mine, or else you make a horrid accusation against your friend. Though I do not pretend myself to understand how the end is to be obtained by the means proposed, yet *I* have not had the inestimable benefit of the author's explanation. You are convinced that he has sent messages from Brighton to London; and he has spent a fortune in doing this thing. Well, now, surely he could send a message from London to Norwood; but why did he not earn that £1,000 from Mr. Cyrus Field, which is spoken of in "A Thor Son's" letter? I suppose he scorned to take money out of a man's pocket in that sort of way, though he *could* have done it as easily as winking,—eh?

You think, then, it would have been better had I left this thing alone. I don't; for, d'ye see, in that case literature would not have been enriched by this moral essay of yours. Instead, you think, it would have been better if I had continued to bewilder people with my "by no means new" theory of force and form. Well, I think I told you at first that it was not my theory, also how old it was, and who the author of it was; of course I did, and then, like a wise man that you are, you tell me back again that it is not new. That is a marvellous discovery on your part, is it not? And very kind of you to return me my own. I cannot tell you how much I am already benefited by your lessons on modesty. But I do wish you could have given us some ideas on telegraphy in general, and on Mr. Haworth's system in particular, it would have been more to the purpose. I have no doubt a man of your kindly disposition would have done so if you had any to give. Well, you have given us what you could; so we must "rest and be thankful." In conclusion, I can only hope that "we may a' think weel o' oursels."

BLANC O'MOUGREVE.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—In looking over some old specifications the other day I found that a Mr. Stanislaus Hoga took out a patent in September, 1857, for "Improvements in apparatus for generating electricity, and for transmitting electric currents from place to place," and his plan appears to me identical with that of Mr. Haworth, but far more simple and plausible. The "apparatus for generating electricity" consists of a hydro-electric machine, in the boiler of which a mixture of mercury and sulphuret of mercury is used instead of water. The apparatus, by which two stations can be brought into electric communication, consists of two small boilers. Near each boiler is

placed an insulated shallow vase filled with water; at one station "the positive electricity of the jets of mercurial vapour" is conveyed to the water in the vase, "to be there dissipated in the air," thus leaving for use "the negative electricity of the boiler;" at the other station, a metallic connection conveys the negative electricity from the boiler to the vase of water, leaving for use the positive electricity of the jets. At each station two large zinc plates are "placed vertically in the ground," at a certain depth and distance apart. The plates of each pair are parallel to each other, and to the corresponding pair of plates at the other station. The upper end of each pair of plates are connected by wire, which passes through a delicate galvanometer, so that the passage of electricity from one plate to the other is indicated by the motion of the magnetic needle. "When the opposite kinds of electricity respectively at each station are in connection with the earth they run together, and pass by the metallic wire of the two plates and the galvanometer;" if, however, the electricity from only one station is in connection with the earth the galvanometer at that station is not affected, but the electricity is "dissipated in the neutral mass of the earth." If the electricity is so abundantly produced at the receiving station that its needle is affected by "the electricity which passes from the first plate to the ground without the co-operation of the electricity of the distant plate," a third plate in the ground is connected with the second plate "by a wire passing through a galvanometer;" there is no connection "between the two first plates." "When the electricity at the distant place passes to the ground, a horizontal current is formed in a line passing the second and third plate," thus affecting "the needle of the galvanometer."—Yours, &c., L. P. R.

INDIA-RUBBER COVERED CABLES.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—The very sensible and straightforward communication of Mr. W. T. Henley, which appeared in your journal of the 6th ult., has left an impression upon all minds that the days of india-rubber are over, and that the futile attempt of your correspondent "Beppo," in your last number, to controvert Mr. Henley's facts was a befitting "wail" on the departure of that noisy candidate for public favour from the field, leaving its too long abused, but successful antagonist in the ascendancy. "Beppo" specially pleads for the "manufacturers" of the defunct india-rubber cable in the Persian Gulf; but why did he not bring forward a single instance in which india-rubber had succeeded? Mr. Henley, a gentleman of great practical experience, states:—"If we bury it (the rubber) in the sea or in the earth it becomes converted into treacle; if you stretch it in the air it shrivels up and peels off the wire." Is such the fact, or is it not? Let "Beppo" prove the contrary.

Yours, &c.,

17th August. R. WATSON.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—I see your correspondent "Beppo" has had a fling at me this week. Why is he ashamed to give his real name? Surely people need not hide themselves behind an anonymous signature. I am happy to inform him my corns have not been trodden upon, as, fortunately, I have none. Neither was I "afflicted with a spasm of asperity" when I wrote my former letter. Neither was it written under inspiration, as your correspondent suggests, but "after quiet, calm consideration," and my only object was to vindicate myself from misstatements, as I did not see the necessity of my being made a scapegoat for other people's shortcomings. They, no doubt, concluded I was too thick-skinned to take any notice. Your correspondent does not state facts when he says the cable had to be finished at such a short notice, and I believe neither myself or men were likely to get into an "awful stew" in making twenty miles of cable, when we can, with the greatest ease, get through nearly twenty miles per day when it is required. "Beppo's" remarks about the burnt tar, and the great bunch knots, are simply absurd; and as regards the seething tar he speaks of as having seen, I again repeat such a statement is in direct contradiction to facts; and as for the tar-pot, I have none. The barrels of tar are emptied into a wooden tank, through which passes a steam-pipe, and it is never heated to such a degree that the man cannot put his hand in it. The tar used is always the best Stockholm, and but a very little heat is required to make it sufficiently fluid to saturate the yarn; and when it goes on the core it is always quite cold. "Beppo" wishes to know the number of miles of gutta-percha cables now at work, and speaks of them as having almost universally failed, and strangely enough alleges this to be the reason why india-rubber cables are so little used. He can easily satisfy himself as to the percentage of cables actually at work, and he will find a very respectable proportion in that condition; and one fact he will find defying contradiction, and that is, in no single instance has a submarine cable ever failed through decay in the gutta-percha. Other causes have contributed to the numerous mishaps in submarine telegraphy; one of the principal has been a false economy, which has led to a stinting of material in the manufacture both of the insulator and its protecting covering, by which the affair has been starved in its birth, and its life thereby reduced to the shortest limit; others have been injured in the manufacture from a want of proper care, whilst some have been ruined in the submergence; but practice makes perfect, and all those sources of failure will be guarded against in future operations; and whilst we can depend on the insulator—which we certainly can in the case of gutta-percha —the remainder is easy. "Good wine needs no bush," and gutta-percha requires no puffing; its advocates are quite content to let it rest on its own merits, leaving the friends of india-rubber to sing praises of that material to their heart's content; but I think they are rather short of certificates of its good behaviour, when one in Messrs. Hall & Well's advertisement (which I suppose has been selected as the best) gives it a rather qualified character when it merely says *it looks perfect*. I apprehend many things are perfect in appearance, which are very far from being so in reality. As I leave for the Adriatic the first thing on Monday, I shall not have the pleasure of seeing what "Beppo" and other friends of the sticky gum may have to say in your next number, until some time after its issue. In the meantime, I can only wish success to the science, and hope "Beppo," and others will see the error of their ways, and apply their abilities to something more promising and profitable than bolstering up the cause of a deceitful material that hides its faults until all the expense and trouble has been incurred of making it into cable, and placing it in an important position, when failure can only bring discredit to all concerned.

August 13th, 1864. W. T. HENLEY.

THE SUBMERSION OF DEEP-SEA TELEGRAPH CABLES.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—There has been during the last few years numerous ingenious contrivances suggested and patented for laying down telegraph cables in deep seas, and perhaps the one which received the most attention is that advocated by Captain Selwyn, R.N.—namely, the employment of a floating cylinder. I have always understood that the idea originated with the gallant captain, but I find that a patent was taken out for a similar plan by a Mr. Lavater, in December, 1857. The inventor states that "the cable was to be wound ashore upon a floating drum or cylinder, to be unrolled out at sea by means of the axles of the drum being fastened by chains to a steam-tug. I should be very glad if you, or any of your readers, would give a full description of Captain Selwyn's proposed arrangement in an early number of the *Telegraphic Journal*.—Your obedient servant,

16th August, 1864. E. MARTIN.

SUBTERRANEAN TELEGRAPH LINES IN FRANCE.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—I notice in your publication of last week, in the article by myself upon the subterranean lines of France, that by some inadvertence the inventor's name is not mentioned. After the second paragraph it should have read thus:—"These underground wires are protected during their whole length by an hermetically-sealed iron tube, the invention of Mr. Baron, inspecteur des lignes télégraphiques, Français, to whom the credit belongs for producing the most reliable system of subterranean lines."

Yours truly,

Paris, 16th August, 1864. D. E. HUGHES.

THE ELECTRIC LIGHT.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—Would you be good enough to inform me, in your notes to correspondents in your next issue, what battery you consider the best, *taking the cost into account*, for showing the electric light. The Maynooth, so far as I am able to judge, is the best, but the noxious fume of the nitric acid is objectionable; and perhaps Daniell's, though costing more at first, is better; but I shall be glad of your opinion. Also, as to the number of cells required to show the voltaic arc for experimental purposes. I suppose the apparatus for keeping the carbons the right distance apart will be an expensive one—that is, that which is self-acting.—I am, Sir, yours truly,

Southport, August, 1864. A CONSTANT READER.

[Our correspondent will find some useful information concerning a new battery recently introduced for lighting purpose, on reference to our column of telegraphic news.—ED. *T. J.*]

TELEGRAPHIC NEWS.

THE TELEGRAPH IN CHINA.—Many of our readers are, doubtless, acquainted with the fact that it is in contemplation to lay down a line of telegraph between Shanghai and Woo-sung. The local native authorities have accorded their permission, and the enterprise will, we understand, when complete, be in some way connected with a Chinese office. The advantages which must accrue from the construction of a telegraph line are manifold. Vessels will be instantly reported to Shanghai as soon as they come in sight at Woo-sung. Vessels which may accidentally run ashore will not be left longer in a perilous position than may be necessary to transmit a message to Shanghai, and send a tug to the rescue. It will, moreover, prove a step towards establishing a line up the Yangtsze, to the north, and eventually to Hong Kong. The sharp end of the wedge having once been inserted, the rest will naturally and easily follow. It is also worthy of notice that railways and telegraphic lines generally follow one another. We may, therefore, expect to see a railroad opened within a few years, and then the subjugation of China by European civilization will be an accomplished fact.—*London and China Telegraph.*

Application of Electricity in Warfare.—The terrific explosion of the mine under one of the defences of Petersburg, and which proved so disastrous to human life, was effected by electro-magnetism, the apparatus employed being similar to that employed by the royal engineers at Chatham, the invention of Professors Wheatstone and Abel.

Telegraph Clerks' Provident Fund.—The above institution gave a conversazione, on the 8th ult., at Barnsbury-hall, Islington, which was exceedingly well attended. The chair, in the early part of the evening, was occupied by George Sheward, Esq., one of the directors of the London District Telegraph Company, and of the London and North Western Railway Company, a gentleman who has at all times evinced the greatest solicitude for the welfare of telegraph employés, and who, on this occasion, fully explained the object of the Fund, and gave a very cheerful account of the progress already made. On the conclusion of the chairman's address the programme of the evening was proceeded with, which consisted of the following selections:—Pianoforte duet, Misses Eden and Drew; song, "Sweet Spirit hear my Prayer," Miss A. Stanhope (accompanied by Miss Drew); dramatic selection from "Lady of Lyons," Mr. James Cook; duet, Misses Bristow; an address, Mr. John Young; song, "My Nannie 's awa'," Mr. Thos. Hood; "The Song of Slavery," Mr. Jas. Cook; Song, "Annie Lisle," Mr. Bowyer; "A Parental Ode to my Infant Son," Mr. Jno. Young; illustration of the late Mr. T. Hood's poem of "Skying a Copper," in the character of *Sarah Ann Grubbles*, a housemaid, by Mr. Jas. Cook; song, "Kathleen Mavourneen," Miss A. Stanhope (accompanied by Miss Drew); song, Miss M. Eden; the roaring farce, entitled, "Number One, Round the Corner,"—*Nobbler*, Mr. W. Coleman; *Flipper*, Mr. R. J. Garrard; *Jem*, Mr. W. Simmonds; *First Floor Lodger*, ——. National anthem.—The pianoforte duet by the Misses Eden and Drew was deservedly applauded, and Miss A. Stanhope (accompanied by Miss Drew) elicited the liveliest marks of approbation, the songs being rendered with a depth of feeling, taste, and sweetness not often to be found at amateur performances. The Misses Bristow also contributed to the pleasures and delight of the evening by a well-executed duet, which was rapturously applauded. The gentlemen also sustained their respective parts of the programme with admirable effect and ability. Mr. Hood is an excellent singer, and was enthusiastically encored and cheered. Mr. Cook recited some dramatic selections from the "Lady of Lyons," and, in the character of *Sarah Ann Grubbles*, subjected the "risible faculties" of his audience to a lively and refreshing exercise. Mr. John Young delivered an address explanatory of the objects of the institution, and we regret our inability to place the same before our readers, not having been favoured with a copy. "The roaring farce," entitled "Number One, Round the Corner," in which the members of the International Dramatic Club appeared, was exceedingly well performed, and provoked mirth in abundance; Mr. Coleman—the comical *lion*—as usual sustaining his part with marked ability, amidst *roars* of laughter. The evening was pleasantly wound up with a merry dance, to the lively music of Miss Drew, the accomplished and obliging pianist. It is seldom that we have had the pleasure of joining an assembly where so much good and friendly feeling appeared to exist, and we hope that such efforts to bring together, for mutual benefit and advantage, so numerous a class of public servants, will be persevered in, and that the worthy example shown by Mr. Sheward will be speedily followed by others of the directors of telegraph companies. We were sorry that the esteemed and indefatigable secretary of the institution was prevented from being present owing to severe illness.

Blasting an Immense Chalk Cliff by the Royal Engineers.—For several weeks past a number of Sappers and Miners from the Royal Engineer establishment at Chatham, in charge of Lieutenant Thomas Fraser, have been employed in sapping and mining for destroying a portion of an immense cliff of chalk at Halling, in the occupation of Mr. Thomas Weekes, lime and cement manufacturer, near Rochester, the cliff being the property of the Earl of Darnley. The engineer officer and men have been daily employed in driving galleries and sinking shafts, and all the necessary preparations for the blasting of the cliff were completed on Saturday night last. The chalk to be removed is estimated to amount to about 100,000 tons; and some idea may be formed of the immense blast required to dislodge such a huge mass, when it is stated that the quantity of gunpowder used in the operations weighed in the aggregate 5,400 lbs., distributed in five charges. There were four immense shafts bored in the summit of the cliff, and these were carried down to a depth varying from 64 feet to 25 feet in the chalk. In order to prevent accidents on the occasion of the explosion, the ground, for a considerable distance round the base of the cliff, was kept clear by soldiers. The battery for transmitting the voltaic current to the charges was placed about 200 yards from the shafts, the spark being conveyed by wires coated with gutta-percha from the battery known as Groves's, having forty cells. The operations for blasting the cliff took place on the 16th instant, and nearly all the principal officers of the Royal Engineers were present on the occasion. Colonel Harness, C.B., the director of the Royal Engineer establishment at Brompton; the Earl of Darnley; Colonel T. B. Collinson, instructing engineer officer; Colonel J. F. M. Browne, C.B., field officer of military discipline; Colonel Lovel, C.B., and many other officers of distinction were present. The effect of the explosion was not only grand, but wonderful; the whole crown of the extensive rock was lifted up several feet, and the ground for some distance vibrated under the feet of the numerous body of spectators, and everything went off very satisfactorily. The chalk thus blown down is some of the best for lime and cement purposes, and, of course, very valuable.

Telegraphy in France.—Efforts have been made to consolidate the post-office and telegraphic services in France; but, owing to the strong opposition evinced on the part of the chief functionaries of both services to such an amalgamation, it appears that the idea has been for the present relinquished by the imperial Government.

Telegraph across British North America.—The Hudson's Bay Company lately appointed the Arctic explorer, Dr. Rae, to visit the country between Red River and the Pacific coast, to select the proper line for the telegraph. That gentleman reached Fort Garry about a month ago, and is now far on his way across the plains of the Saskatchewan, and we are now enabled to make the further announcement that 77 tons of wire, nearly half the quantity required, have arrived at Montreal, and the balance will be here very shortly. The wire is to be forwarded at once by the Grand Trunk Railway Company to Sarnia, and by steamboat to the head of Lake Superior, whence it will be transported next winter to Fort Garry on the Red River, at which place the whole of the wire, insulators, &c., will be collected by the beginning of the spring.—*Montreal Gazette.*

India-Rubber Covered Cables for Government.—The War Department of her Majesty's government have recently been supplied with a length of telegraph cable for use, we believe, in some of the new experiments about to be instituted. This is a multiple cable having two conductors, each one consisting of a strand of seven No. 24 copper wires, insulated with india-rubber to a total diameter of three-eighths of an inch. The two cores thrown together are then served with yarn, and neatly braided over with the same material, the yarn having been previously well saturated with tar, and allowed to get perfectly dry before application, in order to prevent it injuriously affecting the rubber. The choice of india-rubber telegraph cables evinces an enlightened appreciation, on the part of the authorities of the War Department, of the advantages this material offers as an insulator, and demonstrates, moreover, their satisfaction with the cables heretofore supplied,—this making the sixth of a series which have been brought into use in various ways, and which indeed have rendered the most efficient service in the numerous important experiments already made known to the public. This cable, in common with all previous ones supplied to the War Office, was manufactured by Messrs. Wells & Hall, and is made in strict conformity with their patent. It is but just to observe that they are all in perfect preservation, and with every appearance of continuing so. With so many gratifying evidences of the excellence of this method of manufacturing cables, we may venture to indulge the hope that it will speedily be tried on a more extended scale, and be successful in solving the great problem of ocean telegraphy.—*From a Correspondent.*

The Electric Light.—At a meeting of the Inventors' Institute, Mr. J. Dickson read a paper "On Certain Inventions for Insuring the Economical and Efficient Production of Voltaic Electricity for Lighting Streets and other Purposes." The object of the paper was to explain the means by which electricity could be readily and economically produced. The history of voltaic electricity was carefully traced from the time of Volta, from whom this form of electricity took its name, to the present time, special mention being made of Grove's, Smee's, the Maynooth, and other batteries, which from time to time have been looked upon as vast improvements upon then existing apparatus. The theories of Mayer and Joule were referred to, as well as the researches of Professor Tyndall, whose "Heat as a Mode of Motion" contains so much valuable information upon the subject. He considered that the rapidity of the vibration of the atoms in a conductor was exactly in proportion to its conducting power, and explained that, whilst a battery was producing light and heat, less material was being consumed than when the battery poles are directly connected with each other. Mr. Dickson's battery was described as one of the hot-class—the sulphuric acid was heated to 600° Fahr. He claims, by his mode of applying heat, to be able to use iron and other cheap metals, instead of the dear ones—zinc, copper, &c. The relative mobility of the atoms of an electrolite determined, he considered, its force rather than its specific gravity. When oil of vitriol was heated to 350° Fahr. only, the electric action is less powerful than when heated to 600° Fahr., probably owing to the waves being less rapid. With the necessary percolating apparatus he was convinced that his battery would be successful for lighthouse purposes. He considered 15 to 20 of his cells equal to 20 to 22 cells; 3 of his cells are not equal to 2 of the nitric acid cells, but the increment in his battery was greater. Grove's battery cost 1s. 5d. to produce the same amount of electricity as that produced for 10½d. by Dickson's. Comparing the lighting powers, 11½d. with the caloric battery will produce the same amount of light as 1s. 5d. by Grove's. He declared that the sulphur liberated at the negative poles could be reconverted into sulphuric acid to the extent of $\frac{19}{20}$ths. The oil of vitriol during the working of the battery becomes combined with water, but the acid is easily and cheaply reconcentrated. In Smee's, Daniell's, and Grove's battery the sulphate of zinc cannot be recovered, whilst in his caloric battery the recovery was not difficult. The chairman expressed the fear that the invention promised so much, that he was no more likely to perform it than to obtain perpetual motion; indeed, if the invention were not overstated, they would certainly be nearer perpetual motion than they had ever been before. Mr. Varley suggested that, as the principal feature in the invention appeared to be the heating of the materials, it was not impossible that it might be as great a step in advance as the introduction of the hot-blast in the manufacture of iron; this, of course, remained to be seen. The new light was exhibited at the meeting on the 18th of February, when an opportunity was afforded for examining the caloric battery in operation.

Telegraphy in South Australia.—Mr. Todd, superintendent of telegraphs, is preparing a report respecting a telegraph line to the northern coast, to be constructed in conjunction with the other colonies.

The Telegraph in Persia.—We have just waded through certain papers published in return to an address of the House of Commons, dated February 15th of the present year, and we are fain to admit that the impression left on us by their perusal has been anything but favourable to the manner in which the present government appears to conduct our affairs abroad, and to its mode of rewarding those who have rendered it sterling service by bringing a most important matter to a successful issue, when the officials first entrusted with its management had signally failed to accomplish the desired end. The documents we allude to are those connected with the convention ratified by both the English and Persian Governments in February, 1863. The subject of the convention was the telegraphic line through Persia, and although Lord Russell appears to have commenced his negotiations with the Teheran government, through Mr. Alison, in May, 1861, that officer having reported his inability to effect anything in April, 1862, this most vital question remained in abeyance until brought to a satisfactory termination by the energy and diplomatic skill of Mr. Eastwick, on the 19th of December, 1862. After his first failure, Mr. Alison rested on his oars until fresh injunctions from his chief of the Foreign Office obliged him to address the Persian government anew, in September, 1862. After upwards of a month spent in "*des pourparlers qui n'aboutissaient à rien*," Mr. Alison left Teheran for the good of his health, and pending Mr. Eastwick's return from Meshed, the capital of Khorassan, whither he had gone on a special mission with reference to the invasion of the Herat territory by Dost Mahomed Khan, Mr. Ronald Thomson, the Oriental secretary, became *pro tem.* chargé d'affaires. Mr. Thomson was not more successful with the Persians than her Majesty's ministers, and yet Mr. Eastwick almost immediately after his return, and whilst suffering from severe ill health, induced by the climate and exposure, and by the rough travelling, bad food and lodging, for which Persia is infamous, managed with great tact to obtain the consent of his Majesty the Shah to a convention, which entitled the British government to ensure its connection with its empire in the East by means of a line of telegraph through Persian territory. It is then to Mr. Eastwick, and to him alone, that we are indebted for this benefit—one that we can never prize too highly, when we reflect how much of the well-being and happiness of our own folk at home depends upon the security of our Eastern possessions. We regret to notice that after Mr. Eastwick's sudden and unexpected departure from Teheran, and Mr. Alison's subsequent return to the seat of his mission, an attempt was made to substitute a new convention for that already agreed to by Nazir-ood-deen Shah, but at the same time we are well pleased to observe that the Persian minister objected *in toto* to any change in the arrangements made by Mr. Eastwick, who is, therefore, still the man the British public ought to thank for a genuine service effected under difficulties of which no one who has been unaccustomed to Persian wile, prejudice, and fanaticism, can form any accurate idea. As to Mr. Eastwick's reward for the above service, we are not as yet aware that it has been in any way commensurate to its merits. We, on the contrary, see that an attempt was made by Mr. Alison after his return to Persia to show the existence of inaccuracies in Mr. Eastwick's translation of the convention; what Mr. Alison's motives in doing so were we dare hardly say, but we should be glad to see all the reasons of Mr. Eastwick's removal from his post at Teheran brought prominently brought before the British parliament. —*Morning Herald.*

MISCELLANEA.

A Costly Patent Law Suit.—The great paraffin case of Young *v.* Fernie is said to have involved an expenditure of about £40,000.

How to Work.—It is better to accomplish perfectly a very small amount of work than to half-do ten times as much.

Dissolving India-rubber.—It deserves to be generally known that petroleum is an excellent solvent of India-rubber, and is 50 per cent. cheaper than benzole.

Peals of Bells.—A correspondent of the *Builder* says:—"We have now in London and different parts of the United Kingdom about 14 peals of twelve bells, 50 peals of ten bells, 600 peals of eight bells, 700 peals of six bells, about 400 peals of five bells, and a great number from one bell to a chime of four bells; and all these peals of five to peals of twelve bells cost each from £300 to upwards of £2,500. So you see what a merry ringing island England is; and a melodious peal of bells is perhaps not less captivating than the finest toned instrument ever yet invented."

The New Metal.—Magnesium was discovered by Sir Humphrey Davy in 1807, but remained little else than a chemical curiosity until 1862-63, when Mr. Edward Sonstadt patented a series of processes, whereby it may be produced in any quantity. Magnesium is a metal white as silver, and very light, its specific gravity being 1·74, or about one-fifth the weight of copper. In the form of wire it may now be purchased at 3*d.* per foot at all the principal metallurgists, opticians, and photographic material dealers. If the end of a piece of wire be held in the flame of gas or candle, it at once takes fire, and burns gently with a dazzling white light, by which a photograph may be taken with a perfection equal to sunshine. The wire supplies an excellent specimen of the metal, and the burning of a few inches is a brilliant and interesting experiment.

Silence in Nature.—It is a remarkable and very instructive fact, that many of the most important operations of nature are carried on in unbroken silence. There is no rushing sound when the broad tide of sunlight breaks on a dark world and floods it with light, as one bright wave over another falls from the fountain, millions of millions of miles away. There is no creaking of axles, or groaning of cumbrous machinery as the solid earth wheels on its way, and every planet and system performs its revolutions. The great trees bring forth their boughs and shadow the earth beneath them, the plants cover themselves with buds, and the buds burst into flowers, but the whole transaction is unheard. The change from snow and winter winds to blossoms and fruits and the sunshine of summer is seen in its slow development, but there is scarcely a sound to tell of the mighty transformation. The solemn chant of the ocean, as it raises its unchanged and its unceasing voices, the roar of the hurricane and the mighty river, and the thunder of the black-browed storm; all this is the music of nature—a great and swelling anthem of praise, breaking in on the universal calm. There is a lesson for us here. The mightiest worker in the universe is the most unobtrusive.—*Brakus.*

TO CORRESPONDENTS.

J. H. G.—Received with thanks. Any further information concerning telegraphy will be highly esteemed.

D. E. H.—We regret that a clerical error should have partly vitiated the contribution, and that it was impossible, at the date on which your letter was received, to make the proposed arrangements, the type having been distributed.

K. R.—We shall insert a list of all existing telegraph companies next week, and shall feel obliged in the meantime for information respecting change of officers or offices which may have recently taken place.

J. Sanderson.—Means are now extensively adopted in the metropolis and elsewhere for uniting police and fire-offices by electric telegraph. We believe that there are several large establishments in London who maintain a telegraphic communication with the chief or subordinate offices of the fire establishment. As you have not described the instrument you propose to employ for effecting instantaneous communication between public and private establishments, we cannot offer an opinion as to the practicability of insuring it by letters patent.

A Subscriber.—Back numbers are kept on hand, and may be had from the publishers.

As information respecting Improvements, Extension of Lines, and Progress of New Undertakings will at all times be most acceptable, we hope that our readers will kindly render us assistance, by furnishing us with brief notices of events and occurrences in connection with electrical and scientific progress.

Communications intended for publication must be authenticated by the names and addresses of the writers; not necessarily for insertion.

Letters relating to Advertisements are to be addressed to the Publishers. All other letters and communications to be addressed to the Editor of the *Telegraphic Journal*, 4 & 5, Suffolk-lane, Cannon-street, London, E.C.

The *Telegraphic Journal* can be had of Messrs. Smith & Co., Strand; J. Onwhyn, Catherine-street, Strand; Messrs. Dawson & Co, Cannon-street, E.C.; Messrs. Kent & Co., Paternoster-row, London. Messrs. Heywood & Co., Manchester; at the various railway stations; and of all news-agents, &c., &c.; or it can be supplied, if preferred, direct from the Office on the following terms:—

Quarterly, 4*s.* 4*d.* | Half-yearly, 8*s.* 8*d.* | Yearly, 17*s.* 4*d.*

TO ADVERTISERS.

Advertisements must be delivered to ensure insertion before Seven O'Clock on Thursday evening in each week. The charges for Advertisements are—

FORCE AND FORM.

CONTRIBUTED BY B. O'M.

VI.

HAVING now arrived at the full form of our atom, it is necessary that we bring some confirmations in support of it from experience. This we shall do from electricity and magnetism.

That matter is not formed of hard, unalterable atoms can, as I think, be proved by electric conduction, and has been so proved by Professor Faraday, somewhat in this way:—Some substances contain more matter in the same bulk than others, or which is the same thing there is a difference in the specific gravity of different substances: as, for example, platinum and silver. There is no substance that is not capable of compression, neither is there any that is not capable of expansion. This being so, then on the theory of hard, unalterable atoms there is no substance in which the atoms that compose it are in contact; therefore, in all cases, matter is composed of solid atoms and void spaces. This must be so; for on this supposition all material atoms are unyielding, therefore not elastic or contractile and expansible.

Now if matter be composed of hard particles or atoms, and void spaces, it must be by means either of the hard particles or of the spaces that matter conducts electricity. Taking silver and platinum. Now silver is a ten times better conductor than platinum; but platinum contains more matter, bulk for bulk, than silver; therefore it would appear that it is the void spaces in silver which constitutes it a better conductor than platinum. Now take silver and gumlac. There is more matter in silver than in gumlac, bulk for bulk, but silver is a million times a better conductor than gumlac; therefore it would appear that it is the solid atoms in silver that makes it be a better conductor than gumlac; so that in silver the hard particles are better conductors than the spaces, and also the spaces are better conductors than the hard particles: which is absurd. But there is one hole for escape, namely, that all atoms are not of the same density; that the atoms of each simple substance have their own specific density. Now as silver is the best conductor of electricity, it must be either because it contains a greater number of atoms, bulk for bulk, or greater spaces; for density is put out of the question, that is accounted for in the atoms themselves. If the great number of atoms in a given space gives it its conducting power, then it must be the least compressible of all substances; or if there be any substance less compressible, that substance must be a better conductor. Glass is a less compressible substance than silver, but glass is a worse conductor of electricity; therefore it must be the great inter-atomic space of silver that gives it its conducting power. Then silver will be the most compressible of all substances, or if there be one that is more compressible, that will be a better conductor. India-rubber is a more compressible substance than silver, but india-rubber is a worse conductor; therefore, again, the atoms conduct better than the spaces, and the spaces better than the atoms: which is absurd. The only escape is, that matter is not so constituted. Again, it is not possible for the atoms to conduct, for in no case is there continuity; it is in the spaces only that there is continuity; therefore, of the two, the spaces are more likely to be the conducting medium; but then, in that case, a vacuum ought to be the best conductor, but it is the worst. Therefore on none of these suppositions can the facts of conduction be explained, and if there be any other supposition possible, which will make hard atoms and conduction agree, then I should like to see it. Just one more argument against hard atoms. Since on no substance do the atoms that compose it touch each other, by what means are they held in proximity, or how were they brought into that proximity? It is said, by *attraction*. Then what prevents them from being brought into contact? It is said, repulsion. That is, attraction up to a certain point, and then repulsion after that! But is not this "pulling without hold, and pushing without touching?" Or rather, is it not an absurdity?

Unyielding, unalterable atoms then, are not in agreement with facts and reason. Let us see how ours will cover the facts, and thereby satisfy reason. But first, our confirmations. The magnetic sphere of potency is an apt illustration of our atom, though the magnetic sphere is in the elemental series; still the law is the same generally, though differing by discrete degrees of forms.

Take a symmetrical bar magnet, and place over it a card; upon this card sift iron filings, and gently tap the card till the iron filings arrange themselves according to the magnetic lines of force, as in Fig. 1.

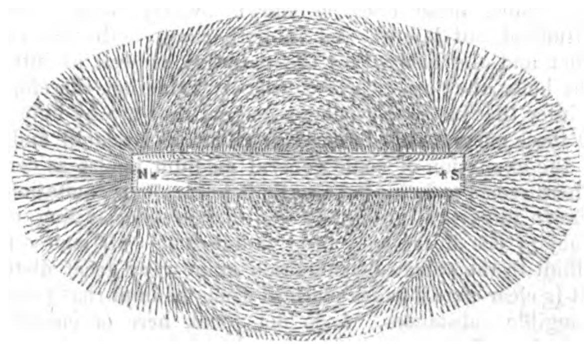

FIG. 1.

At first sight the fluxion of this force will not appear to resemble the fluxion of our atom; but when analysed we shall see that it is so. In the first place, in all permanent artificial magnets, that I have examined, the poles are not at the ends, but a little way from them. In this instance they are at S and N; therefore the true magnetic sphere extends no further than these; consequently the true magnetic sphere may be considered as extending no further than the complete curves terminating in N and S. This will leave a sphere similar to that in Fig. 2.

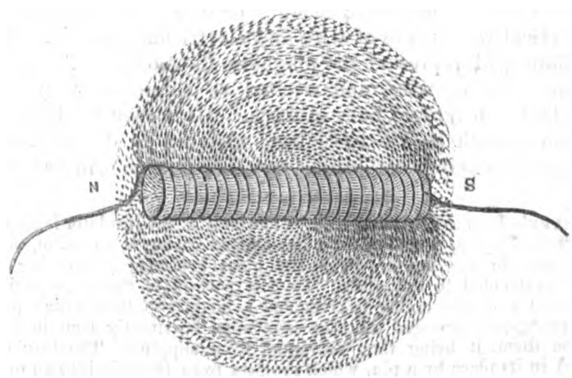

FIG. 2.

This is a simple coil of insulated wire, on a piece of wood.

If arranged as the preceding magnet, represented in Fig. 1, and then a current of electricity passed through it, the sphere of magnetic lines of force will be represented as in Fig. 2. Reverting now to Fig. 1, it will be seen that the lines of force pass from N to S, as meridians, whereas in our atom they spirate laterally. We have no means of showing this sphere of force adequately, but by means of iron filings; of course very small magnetic needles would show the same, but that is really what these filings become. Now it is a well-known fact that a small bar magnet, or particle of iron, if at liberty to move, will arrange itself across a current of electricity, and at right angles to it. Now look at Fig. 2, and you will see that this is just what these small particles of iron have done. Then by inference can you not see that there must be just such currents round the artificial magnet, represented in Fig. 1. There is no difference between sphere Fig. 1, and sphere Fig. 2, except this, that sphere Fig. 2 is more perfect than sphere Fig. 1, not having these excrescences at the ends. Why we cannot yet make a perfect artificial steel magnet, I cannot tell at present. Surely one can be made. At least I mean to try.

It has been abundantly proved by Faraday that each magnet contains within it an amount of lines of force equal to the amount it has surrounding it, by means of the electricity excited in the moving loop, and as he has proved it for the permanent magnet; it is also proved for the helex of copper wire, which is a perfect magnet, when electrically excited; therefore within the helex, Fig. 2, there is the same amount of magnetic lines of force as there is surrounding it. Now, as before stated, these lines, as shown by the filings, are not longitudinal, but lateral, and in both cases, both that of the magnet and the helex, they are external as well as internal. In the helex they are clearly caused by induction, therefore we may infer that in the permanent magnet they are by induction. That these currents are induced there can be no doubt, and that it is the excitation of some general medium is also as certain, for there seems to be no precise limit to it; such excitation can be shown to exist at greater or less distances, according to the delicacy of the instrument used to detect it. Of course there is a limit to the sphere of induction at no very great distance, but it is clear that it takes place in some medium that pervades all tangible substances. I do not speak here of electric induction, but of magnetic; for though these two are intimately connected, it is evident that they are separated by a discrete degree of difference: but this by-and-by.

Here then it is plain that you have in a magnet a similar fluxion of force to that which we have seen to ultimate the form of our atom. There are the polar spirals, and there is also the circumferential spiral. To show this more clearly, just take the atomic vortical and enclose the polar spirals in a parallelogram, to represent a bar magnet; then draw meridians from pole to pole, which meridians will pass at right angles across the lateral circumferential spirals, which is the position which a series of small magnetic needles or iron filings would take if the vortical were made of wire and electrically excited. These meridians will represent the magnetic lines of force, and if the vortical were of wire, and excited as supposed, they would really be the magnetic lines of force. Here then we have force in a form, such as we have been striving to describe, which there is no denying, and which no other fluxion will explain.

THUYER'S IMPROVED INSULATOR.—The body of the insulator is composed of a block of glass, protected by a bell-shaped casing of cast iron, through an opening in the top of which the glass projects; the casing being strongly cemented to the glass. To that portion of the glass projecting from the top of the casing is cemented a metal cap, from which projects three prongs, so arranged that the wire must be slightly bent in passing between them, it being thus prevented from slipping. The insulator is secured in its place by a pin, which projects from the pole into an opening in the underside of the glass. Both the cap and casing are thus so completely insulated that there can be no communication between the wire and the pole.

THE MALTA AND ALEXANDRIA CABLE.

By AMICUS.

By order of the House of Commons, dated 9th July, 1863, was printed "A return of the total expense of laying a telegraph cable between Malta and Alexandria, specifying separately the cost of the cable, the expense of laying, and all other items of expense, &c." This paper together with a copy of lease made with Messrs. Glass, Elliott, & Co., was reprinted in a contemporary journal now defunct. The total net cost of this cable was £436,283 10s. 8d., and is leased to the above firm till the 1st of January, 1867. This being the only submarine cable of any consequence really in existence, any information concerning it is always doubly welcome to those who take an interest in ocean telegraphy. The statement of the number of messages forwarded and the aggregate receipts for the years 1862 and 1863, published in No. 30 of the *Telegraphic Journal*, is gratifying as indicating an increased use of the line, which we may further assume is indicative of an appreciation of the advantages it offers. Supposing the cable should last until the lease expires, and the same rate per cent. of increase in receipts should be attained year by year, the amount for the last year of the lease, ending the 1st of January, 1867, would reach the large sum of about £120,000. Of course nothing presents so dazzling a prospect as submarine telegraph enterprise when the calculations are based upon suppositions, not forgetting also to assume that there be no disaster. Doubtless these prospects would in some degree be realised if we could only ensure immunity against failure, and be absolutely certain of being able to obtain good and durable cables. But here is the rub: there is really no trustworthy data on which to build even a conjecture. With the exception of this line there is no long cable in existence, neither home nor foreign; it is to be hoped, however, that another twelve months will change the state of things, and that there will be at least two additional cables that will afford us some idea as to whether they will pay in every sense of the word; but that can hardly be decided until a term of years shall have elapsed. Something very different must be realised from what is presented by the cable in question in order to constitute it, in the strict sense of the word, a paying concern. We know the cost of this cable, and we know also the money value of the work done through it, and here our knowledge stops short.

Taking the most favourable period—the year 1863—it will be seen that the receipts are some 12 per cent. of the capital invested, and providing there were no other side to the ledger this would be pretty respectable, and yet nothing to boast of, seeing that this cable certainly cannot be a long-lived one. At that rate of income the cable must remain in good working order from ten to twelve years ere sufficient would have been received to refund the original outlay and interest thereupon; so that with the same amount of receipts, and reckoning 1863 as an average year for expenses also, we must double that period before the original outlay would be repaid, as doubtless the cost of working the line, and the heavy outlay for repairs which had to be met last year, would swallow far more than half the receipts. It will be remembered that a break occurred in July of last year, and some may be disposed to object to 1863 being considered an average year for disbursements; but it would hardly be safe to reckon on less than one interruption each year: it has averaged that, and may be more. The working expenses of the line must be heavy, and as according to the lease a vessel should always be kept cruising about in readiness to make repairs in case of the cable parting or what not, and that that vessel must be manned, and all the rest of the expenses incurred by a ship that may be ordered, heaven knows where, at an hour's notice, it follows that an extra heavy and constant drain is going on upon the resources of the lessees, and tending very seriously to increase the debtor side of the account. And when a break really does occur, besides the regular crew of this vessel, a bevy of electricians and experienced men in repairing and splicing a cable have to be added.

The lessees have promised a statement of the cost of repairs, or, if not promised, they state why it has not yet been given. It would be very desirable to be in possession of this information; in the meantime, however, we are thrown back upon conjecture, and are left to wonder if the cost of constantly keeping a ship in readiness, and its employment when there is really work for the crew to do in underrunning the cable, &c., bears any proportion to the item termed "ships" in the Parliamentary paper referred to above. "Ships" are set down there at the handsome sum of £110,500. Of course this means for the hire of the ships, not the purchasing of them, as some innocent people thought. It has been stated

somewhere that the reason why this item took six figures to express it was, that it included the time they lay in the docks while the cable, which was originally intended to connect Rangoon with Singapore, was being coiled up, &c.; but having put out to sea, had not proceeded far before the precious freight was discovered in a state of fusion: the percha a mass of pulp, and the copper almost protruding in places like the backbone of a cabby's hack, hence the vessels had to put back to port. It is further stated that these ships, with their cargo (but not the crew), were sunk in order to prevent the 1,400 miles of cable, made at an expense of some £300,000 for core, sheathing, &c., from degenerating into such a condition from increased temperature as to risk its entirely running away, leaving bare bones only, which would of course be useless. By this means it is to be presumed liquidity was prevented, and the cable retained sufficient shape and consistency to be ultimately submerged between Malta and Alexandria. Doubtless this would help to swell the cost; but making every allowance for this, it is an enormous sum of money, and takes us back to cogitate that if "ships" *now* engaged upon the cable, in work and out of work, bear any proportion to "ships" *then*, it forms an important item on the wrong side of the book. But in addition to this amount for "ships," there was paid to the contractors for submersion a further sum of £25,000, so that to get this cable safely to the bottom of the sea cost £135,500, or about £97 per mile! Well, if it was worth this princely sum to get it there, what is it worth to keep it there? If it were worth £25,000 to the contractors for submerging alone, what must the lessees debit underrunning, splicing, and general repairs at? If present operations bear any proportion to the original outlay, it is certainly under-estimating the cost of keeping the cable in working order and general expenses, as absorbing far more than half the receipts for one year; and hence at that rate the cable will not have paid for itself in a quarter of a century—a period of existence which it is simply absurd to expect it to attain. Singularly enough, although the most unfortunate cable ever made, it is yet the only one that can lay the smallest claim to success; strictly speaking, however, it is only successful in so far as it has been laid and signalled through; commercially, it is not so (although it may be to the lessees). "Successful cable" is a misnomer if there be but 5 per cent. realised upon so vast an outlay, exposed to so many risks, and on a work of so perishable a nature; for cessation of signalling, if not attributable to some accident, means decay, or some process analogous thereto, going on in the gutta-percha, and that this is the case we have the testimony of the first electricians in confirmation of. Ever and anon, therefore, the cable must be hauled up for repairs—a dangerous, although indispensable process, by which a cable is only temporarily benefited, but permanently injured; it follows, therefore, that the oftener a cable has to be treated in this way, the speedier will be its total collapse and uselessness.

It certainly would appear from this view of the case that this line can only be added to the list of failures, it being simply one of degree. It certainly demonstrates the practicability of long submarine cables; but unless a better style of cable can be made, and an insulation adopted that will be proof against decomposition, chemical or otherwise, all essays in this line must, commercially speaking, prove failures. Yes, there is one other way of avoiding it, by reducing the original outlay; but in that case ships must not cost £110,500, nor submersion £25,000, nor superintendence £20,000, nor instruments (for three or four stations) £5,000, and so on.

As Parliament and the country must take cognizance of the cost of repairing this cable, the amount will of course be made known—that is, if any member be wide awake enough to direct attention to it; but it may never come to light what the general expense of working the line is unless the lessees choose to publish it, and yet at this crisis of ocean telegraphy such data as this would afford would be in the highest degree invaluable. There is an obvious reluctance, however, to show the debtor side of the account, and this is observable in a great many enterprises of note; the receipts are published with the utmost punctuality, and while money is rolling in both individuals and public companies think all must be right, the thing is paying well, and so forth.

There is no doubt the lessees of this cable will make a tolerable decent thing of it for themselves; they had a taste of the good things before they occupied their present position. But it should not be forgotten that this is public property, and that half a million of money is too serious a sum to be lost sight of, and therefore it is but reasonable they should know, or be in a position to estimate, the probability or the chances there are of refunding the original outlay, whether the lease be renewed, or it lapse into the possession of the Government to work it on a different principle; and further, it would enable the public to judge as to the wisdom and policy of Government dabbling in lines of telegraph, or whether it would not be better to leave it to general enterprise in the manner of our railways and other modern enterprises. There must necessarily be an unacquaintance with such matters in the different Government departments, which will expose them, and through them the country, to too lavish an expenditure of the public funds; and this cable is a pretty good instance of their having to pay "too dear for their whistle." It was a "Tom Tiddler's ground" for those engaged on it, whether as makers or superintendents, for they picked up plenty of gold and silver.

ATMOSPHERIC PRESSURE AS A MECHANICAL POWER.*

IN a recent article in the *Journal*, on "The Use of Air as a Motive Power in Cities," reference is made to various processes for producing a vacuum under a piston, and the inference drawn that they are all too costly, too slow, or, in other respects unsuited for obtaining a popular working force from the pressure of the atmosphere. Of others not mentioned, there is one that may be worth suggesting.

I believe there are no forces but what are designed to be employed in the arts: that all, known or unknown, are to be brought into the service of man; that Nature not only provides them, but, in her applications of them, is their best expositor, and that whatever she effects for herself with one, we can produce it by the same or analogous results for ourselves. On the present occasion, I would refer to the means by which she disturbs the equilibrium of the atmosphere, in the instantaneous condensation of vapour into rain, and the resultant ærial squalls and commotion that prevail in temperate and become so terrific in tropical latitudes. Here we perceive she is doing the very thing we want to do, employing the weight of the atmosphere as an active motive power, neutralising its influence on one spot and accumulating it on another, by forming a vacuum as it were in a cylinder, whose sides pressed together perform the part of a piston with us. Not a day, probably not an hour passes, in which these phenomena do not occur in one part of the earth or another.

The fall of rain does not appear to depend on temperature alone, since it comes down night and day in all weathers, in summer as in winter, and in the warmest climes in actual torrents. The influence of electricity over atmospheric phenomena is universally admitted, and by some, if not by all meteorologists, it is deemed the immediate cause of rain. That tempests, hurricanes, tornadoes, &c., arise from the vacuum thus suddenly produced, is still more generally conceded. They are commonly accompanied with thunder and of brief duration, subsiding as the voids become filled and the equilibrium restored. In some regions where thunder is little known, it is said there is little rain. Now, why may not artificial clouds of vapour—of low steam in a cylinder—be as quickly collapsed into water by the same means, and vacuities produced to serve our purposes as Nature produces them to serve her own? I suppose they may. If some element should be wanting in the process, it is our part to supply it. If air, for example, be found essential, a limited quantity might be admitted. If the condensation should not be effected as rapidly as anticipated, the area of the piston might be proportionally increased, and so with regard to other points. Electricity, as a science, is in its infancy. It has opened some of Nature's secrets, but they are few compared to those yet to be explained. Among them is the part it plays in the phenomenon in question. If, as is asserted, it causes the aqueous corpuscles suspended in the atmosphere to coalesce and descend, sometimes in drizzle as through the finest cullender, at others in showers of large drops, and again in sheets as if from the bursting of water-spouts, we ought to be able to bring out kindred results by it to establish the theory.

But, without reference to any theory, the object is to learn how Nature effects those sudden collapsions of vapour. Be the process what it may, mechanical or chemical, or a combination of both—whether clouds surcharged with moisture are discharged by compressure, somewhat as we squeeze a saturated sponge or wring out wet linen, or whether it be, as suspected, an electric talisman that neutralises the power that keeps the aqueous globulus apart and holds them in suspension, or anything else—when thoroughly known, we can certainly master it sufficiently to work out on

* By a Correspondent of the Journal of the Franklin Institute.

smaller scales, the same result. If, when developed, it should not be found preferable to processes we have, it is still worth finding out, were it but to determine that fact. But if, on the other hand, it should turn out much better than the best of them—simpler, cheaper, and more prompt, and there should be no obstacles to its general adoption—the benefits it would confer on our species for all time to come, would surpass those of other forces combined, steam included. It would meet almost every call for labour, for domestic and manufacturing drudgery, indoors and out. In a word, I can hardly imagine a nobler acquisition in practical science than the derivation of a general working power from the pressure of the atmosphere. A stronger stimulus to solve a great problem there cannot be.

It is, probably, in some such indirect way as this that electricity, in one or more of its forms, is to become, if ever, a popular motor, not directly, as has so often been attempted, and as often failed. Let us use it as nature does, and we are sure to succeed.

ABRIDGMENTS OF SPECIFICATIONS RELATING TO ELECTRICITY AND MAGNETISM, THEIR GENERATION AND APPLICATION.

IV.

A.D. 1851.—General Sabine, in 1851, drew the following conclusions from the magnetic observations made by the English and Russian Governments:—That the terrestrial magnetic force has periods respectively of—1. A solar day of 24 hours; 2. A solar year of 365 days; 3. Ten solar years. From this it would appear that the sun is a great magnet, and that it communicates to the earth its magnetic properties. (See *Encyclopædia Britannica*, 8th edition, art. Magnetism, p. 18.)

A.D. 1852.—Mr. John Adie, in 1852, constructed a variation compass in which the needle was suspended within a tube. Mr. Swan employed a different arrangement of the same principle. (See *Encyclopædia Britannica*, art. Magnetism, p. 80.)

A.D. 1856.—Professor Tyndall, in 1856, proved the existence of diamagnetic polarity. (See De la Rive's *Treatise on Electricity*, Vol. III., pp. 729-740.)

ELECTRICITY.

Under this head is included static or tension electricity, current electricity, and induced electricity in their various forms; also the results of combining electric force with magnetic force (electro-magnetism), with chemical action (electro-chemistry), with heat and light (electric blasting, electric light, &c.), with mechanical force (electric telegraphy, electro-motion, &c.), and with vital force (medical electricity, &c.)

The production or development of electric force in nature, and its existence and use prior to the researches of man, will be evident to most minds; the following examples bear upon this point:—*Static or tension electricity* in the form of lightning; *current electricity*, as developed by galvanic circuits acting in the natural formation of minerals, also as developed by thermo-electric circuits formed by the unequal temperature of the earth; and *induced electricity* (developed by other electric currents and by terrestrial magnetic force in conjunction with mechanical motion), believed by many astronomers to be included in the category of forces which bind planets to their primary, and system to system. As in magnetism, electricity was first believed to belong to one body exclusively, viz., amber; other "electricts" (as glass, resin, sulphur, &c., all non-conductors) were next recognised; it is now, in its various forms, known to pervade the whole of nature, and to administer silently but effectually to the wants of man.

Holy Writ makes mention of lightning in the following passages:—*Exodus* xix. 16; 2 *Samuel* xxii. 15; *Job* xxxvii. 3; xxxviii. 25; xxxviii. 35; *Psalms* xviii. 14; lxxvii. 18; xcvii. 4; cxxxv. 7; cxliv. 6: *Jeremiah* x. 13; li. 16; *Ezekiel* i. 13, 14: *Daniel* x. 6; *Matthew*, xxiv. 27; *Luke* xvii. 24; *Revelations* iv. 5; xi. 19. Thunder is mentioned in the following passages:—*Exodus* ix. 23, 28, 29, 33; xix. 16; xx. 18; 1 *Samuel* vii. 10; xii. 17, 18; 2 *Samuel*, xxii. 14; *Job* xxvi. 14; xxxvii. 5; xl. 9; *Psalms* xviii. 13; lxxvii. 18; lxxxi. 7; civ. 7; *Isaiah* xxix. 6; *Mark* iii. 17; *John* xii. 29; *Revelations* vi. 1; x. 3; xix. 6. The wonderful passage from *Job* xxxviii. 35, "Canst thou send lightnings, that they may go, and say unto thee, Here we are!" (original Hebrew, "Behold us!") seems almost prophetic, when viewed in connection with the electric telegraph.

B.C. 600.—The Etruscans (about 600 B.C.) devoted themselves to the study of atmospheric phenomena in an especial manner, and divided the lightnings into those that came from the earth and those that came from the sky; they are said to have drawn down lightning. (See De la Rive's *Treatise on Electricity*, Vol. III., p. 90; also *Encyclopædia Britannica*, 8th edition, art. Etruscans or Tuscans, pp. 355-361.)

B.C. 600.—Thales, about 600 B.C., is reported by subsequent writers to have described the power of attracting light bodies which is developed in amber by friction. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, p. 41.)

B.C. 341.—Aristotle, about 341 B.C., records that the torpedo "causes or produces a torpor upon those fishes it is about to seize, and having by that means got them into its mouth, feeds upon them." He further adds that this fish "hides itself in the sand and mud, and catches those fish that swim over it by benumbing them, and of this some have been eye-witnesses. The same fish has also the power of benumbing men." (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, p. 41; also *Encyclpaedia Britannica*, p. 530.)

B.C. 321.—Theophrastus, about 321 B.C., mentions that the "lyncurium" (tourmaline?) has similar properties to amber in regard to the attraction of light bodies. Beckmann thinks the "lyncurium" was not tourmaline, but more likely to have been the hyacinth. (See *Encyclopædia Britannica*, 8th edition, art. Electricity, p. 529; also *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, p. 41; also Beckmann's *History of Inventions*, Vol. I., pp. 86-98.)

A.D. 50.—Scribonius Largus (A.D. 50) relates that Anthero, a freedman of Tiberius, was cured of the gout by the shocks of the torpedo. See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, p. 41.)

A.D. 1160.—Eustathius, Bishop of Thessalonica (A.D. 1160), in the scholia upon Homer, relates that, "Walimer, the father of Theodoric, who conquered, as they say, the whole of Italy, used to emit sparks from his own body; and a certain ancient philosopher says of himself, that once, when he was dressing and undressing himself, sudden sparks were emitted occasionally, crackling; and sometimes, he says, entire flames blazed from him, not burning his garments. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, pp. 41, 42.)

A.D. 1600.—Dr. Gilbert, in his work "De Magnete," published A.D. 1600, adds several substances besides amber to the list of electrics, and states that not only light bodies, but all solid bodies whatever, including metals, water, and oil, are attracted by excited electrics. "These experiments he directs to be performed by bringing the excited body near to the end of a light needle of any metal balanced, and turning freely on a pivot like the magnetic apparatus." (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, p. 42.)

A.D. 1617.—Strada, in 1617, published his "Prolusiones Academicæ." In one of these he speaks of a suppositious means of communication between two friends at a distance from each other. "Strada's fancy was this: there is, he supposes, a species of loadstone which possesses such virtue that if two needles be touched with it, and then balanced on separate pivots, and the one be turned in a particular direction, the other will sympathetically move parallel to it. He then directs each of these needles to be poised and mounted on a dial having the letters of the alphabet arranged round it. Accordingly, if one person has one of the dials and another the other by a little pre-arrangement as to details, a correspondence can be maintained between them at any distance by simply pointing the needles to the letters of the required words." A free translation of the poem, in English heroics, was published in 1750, in "The Student, or the Oxford and Cambridge Miscellany," signed Misographos. (See *Saturday Review*, August 21, 1858, p. 190; also Abbé Moigno's *Traité de Télégraphie Electrique*, pp. 58, 59.)

A.D. 1675.—Boyle, in his "Experiments and Notes about the Mechanical Origin of Electricity," published in 1675, states that warming the electric increases the electrical effect. He also added to the list of electrics, and "ascertained that the converse of all the experiments upon the relative motion of the attracted and attracting body was also true; namely, that if the substance to be attracted were fixed, and the excited electric capable of motion, their union would still take place." (See *Encyclopædia Metropolitana*, Vol IV., art. Electricity, pp. 42, 43.)

A.D. 1675.—Newton, in the year 1675, communicated to the Royal Society the fact that when a plate of glass is excited on one side, the other side also becomes electrical. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, p. 43.)

REPORT OF THE DIRECTORS OF THE SUBMARINE TELEGRAPH COMPANY.

THE directors have much satisfaction in submitting the annexed accounts to the shareholders. It will be observed, on comparing them with the accounts for the corresponding half-year of 1863, that the receipts have increased by £1,737 1*s.* 11½*d.*, and that the expenses are less by £631 6*s.* 4½*d.* The revenue has been charged, as usual, with 10 per cent. on the gross receipts, equal to £2,388 2*s.* 6*d.*, for the reserve fund, which now amounts to £8,907 2*s.* 10*d.* The result enables the directors to recommend a dividend at the rate of 5 per cent. per annum, or of 2½ per cent. for the half-year, instead of 2 per cent., as paid for the six months ending June, 1863. It should be noticed that the sum standing to the credit of the reserve fund, in December last, has been invested in debentures of the North Eastern Railway Company, and Charing Cross Railway Company.

The directors have to inform the shareholders that the Belgian Government has demanded, in accordance with the terms of the Concession, a larger number of wires to London; and, consequently, the directors have laid a branch cable of about twenty miles in length, from the present Ostend cable to the English shore near Ramsgate. This cable has been laid by contract since 30th June, and will be in working order as soon as the land lines are completed. The cost of it, which is about £11,100, will be charged to capital, and will bear its proportion in the distribution of the future nett profits between the Chartered and French companies. The contractor has received, in part payment, debentures bearing 6 per cent. interest to the amount of £4,000, and the directors, considering the present satisfactory state, and the steadily increasing prosperity of the Company, believe that the balance will be also taken up in debentures, either by the shareholders or the public.

By order, S. M. CLARE, Secretary.

THE SUBMARINE TELEGRAPH COMPANY BETWEEN GREAT BRITAIN AND THE CONTINENT OF EUROPE (CHARTERED), AND THE SUBMARINE TELEGRAPH COMPANY BETWEEN FRANCE AND ENGLAND, SOCIETE CARMICHAEL ET CIE.

Examined, compared with the books and vouchers, and found correct, August 15th, 1864,

GEORGE COPELAND CAPPER, WILLIAM R. COLE, THOMAS DAKIN, } AUDITORS.

TELEGRAPH CLERKS' FUND.

THE following address was delivered by Mr. John Young at the conversazione given by the above Fund on the 8th inst., and which was referred to in our account of the entertainment last week:—

In looking back at the days of our childhood we can well remember the occasions when indulgence in cake, toffee, and unripe apples has caused indigestion and a thousand other ills to which our flesh is heir. But the remedy which became our fate on these occasions is still more firmly impressed on our recollection, and we can vividly recall the powder which became our fate—not in its scruple form, but cunningly disguised in a spoonful of jam so that the bitter, though wholesome, medicine was masked beneath the seductive currant and raspberry. Our meeting this evening is not altogether unlike the powder concealed in the jam. Our object in thus assembling is to lay before you the claims of the institution to which our chairman has already adverted, but as this might have been considered a somewhat bitter pill of itself, we decided that songs, recitations, and music should be provided as alteratives to the more serious business of the evening. I will promise to make my dose as small as possible, and when you consider the reward you will have in the vocalization of our fair friends, you will bear the infliction in good part.

You are aware that this is the sole institution of any kind open to telegraph clerks generally. Its objects are to afford medical advice, medicines, and pay in sickness, a provision for old age, and a sum of money at death. When we consider the number of persons who compose our profession it becomes a matter of wonder that there should be but a single institution of this nature among us and that one so partially supported. I have long endeavoured to find the reason for this. Are we as a rule indifferent to our best interests? or is it the nature of the telegraph clerk to be reckless and improvident? A moment's thought must convince one and all of us that it is our bounden duty and incumbent upon each of us to make some provision for a rainy day—ill health may overcome the most robust among us. I remember when the first lot of members was enrolled, one of them on being asked when ill last, replied, "Never!" It seemed almost needless for this person to make a provision, but he did so, and within a month was seized with a severe illness that lasted many weeks. You can deduce your own moral here. It is indeed hard in times of ill health to find all sources of income stopped, and thus be debarred from those comforts and even necessaries which are then so urgently required. Believe me, my friends, the only means by which persons of limited resources like ourselves can make any provision of this nature is co-operation! There is much philosophy in the divine precept, "Bear one another's burdens," for in promoting the welfare of those around us we secure in like proportion our own prosperity and happiness. It is to be deplored that so much apathy and indifference should exist among us; we look too much for extraneous support; we want too much assistance from others, and yield too little ourselves; the best help is self-help—it is more effective and confers no obligation. Not that I would for one moment undervalue the assistance we have received from those ladies, headed by the second in the land, or that of several gentlemen, bright ornaments of society, and who amid the more onerous claims of parliamentary, social and scientific duties, have lent a helping hand to our cause. It is very gratifying to observe the names of so many telegraph directors among the patrons of the institution, and the good feeling and generosity thus evinced will give rise in no measured

degree to corresponding feelings of gratitude and increased diligence on the part of those employed. Labour and capital must ever be intimately associated, and whatever promotes the prosperity of the one advances the interests of the other. I cannot withhold myself from referring to the gentleman who occupies the chair this evening. Among many pressing engagements, and at a considerable sacrifice of leisure, he has devoted much time and attention to our objects, and demands not only the thanks of the members themselves but of every telegraph clerk whom he has sought to benefit. But it is no use for friends and well-wishers to labour for us if we are idle ourselves. I would earnestly urge each and all of you to be "up and doing," to co-operate for our mutual benefit. With common cause and common action much might be done to promote our prospects and interests. Let each put his shoulder to the wheel and advance by every means in his power the welfare and prosperity of the telegraph clerk.

THE PERSIAN GULF TELEGRAPH.

(*Concluded from page* 93.)

There remained one or two splices to make ashore to complete the land portion from the landed end to the floating office at Fau. These were all completed by the evening of the 8th, and at 5.30 p.m. of that date Fau spoke through to Bushire, and thus Fau and Bussorah could telegraph to Kurrachee and Bombay.

There remained yet the section between Gwador and Cape Mons (near Kurrachee) to lay, and as the sea-bed is excessively steep there, deepening from twenty or thirty fathoms to five or six hundred in the space of half a mile, it was one requiring special care; besides which the cable remaining in the Assaye, together with all the main cable in the Cospatrick, was eventually expended on this section without reaching Cape Mons, so that two ends had to be buoyed.

The unsatisfactory state of the land lines between Bussorah and Bagdad, and the complication of political affairs connected with it, required the presence of Colonel Stuart and Sir C. Bright at Bagdad, and the operation of laying this last section was, therefore, entrusted by Colonel Stuart and Sir C. Bright to the superintendence of Mr. F. C. Webb, Mr. J. C. Laws being in charge of the electrical department.

On the 12th, all arrangements having been made, and all the necessary official orders issued, the Coromandel, with Colonel Stewart, Captain Stewart, Sir C. Bright, Colonel Pelly, and Colonel Goldsmid, left for Bussorah. On the evening of the 13th the Zenobia, with the Assaye and Said in tow (to save coal) steamed for Bushire, the Amberwitch having started the same day. On the 15th the Assaye reached the Bushire Roads, and started again on the 16th, and arrived off Luiga on the evening of the 18th. The Zenobia then went to Bassidora (distant about seventeen miles) to coal, and left Luiga on the 24th, with the Assaye in tow, calling at Mussendom, and arriving at Gwador (East Bay) on the 28th. In the meantime the Amberwitch had preceded her with Mr. Webb on board, and arrangements were made for the landing of the end.

The shore end for this section was on board the Amberwitch, which ship was accordingly anchored about half a mile from the shore, and cable coiled from her into the paddle-box boats. A heavy S.W. swell rolled now round the point into the bay, causing the Assaye and Zenobia to roll very heavily, and it was not until the 30th that the latter vessel could attempt to coal. On the 30th, at daylight, the Amberwitch was moved nearer to the shore, and the shore end payed out from the boats to the shore and safely landed. The Amberwitch was then steamed out towards the Assaye, paying out cable as she went, and then hung stern to stern to the Assaye, which ship was three miles and a half distant from the beach. One mile and a half of shore end was then turned over on board the Amberwitch, and the next morning (the 1st of March) this was cut, and the end passed on board the Assaye, and joined on, by means of a taper and two splices, to the cable on board the Assaye; the whole of this one mile and a half was then hauled on board the Assaye, and coiled down on the tops of the rest of the cable, and the bight let go from the Amberwitch at 4 p.m., thus leaving the Assaye with five miles of shore end spliced on to her main cable, and the end safely landed. This was the first case where the shore end of a section about to be laid was payed out from the shore to the large ships, instead of *vice versâ*. The necessary arrangements had then been made between Mr. Webb and Lieutenant Carpendale (the senior naval officer), Commander Bradshaw, R.N. (surveyor), Lieutenant Stiffe and Mr. Young (surveyor), as to the buoying of the course. The Amberwitch was to go on ahead, and take up certain positions indicated on the chart, hoisting a blue ensign at the main when in position by day, and burning blue lights and exhibiting three fixed lights at night.

The hour of departure was arranged to be 4 p.m. of the 2nd, in order to make a dangerous rock near the course of the cable by daylight, but this was altered to 4 p.m. of the following day (the 3rd), on account of some operation to the land line which had to be performed on the shore.

On the 3rd, at 4 p.m., the Zenobia took the Assaye in tow, and at 5 p.m. paying out again commenced, the Amberwitch having started several hours before, and gone on ahead to take up her position, No. 1. At about 10 p.m. the blue lights of the Amberwitch, in position No. 1, were sighted, and the Zenobia steered out towards her.

There was a good deal of swell on, and as the ships pitched the cable jerked, as it generally does in shoal water when there is any sea on. A little after daylight Astola Island was sighted, and the Amberwitch took up position No. 2, which was passed about 8 a.m.

The Amberwitch, in position No. 3, was passed about noon; No. 4, about 4 p.m.; and she was sighted taking up her position, No. 5, about 6.30. During all this time the paying out had proceeded beautifully, the cable sweeping grandly round the tall cone in the middle of the magnificent main coil of the Assaye.

And now came one of the most exciting incidents of the whole cruise. About 7 p.m., with very little warning, the ships were struck by a tremendous squall from the W.N.W., accompanied by rain, lightning, and a fearful quantity of fine sand which enveloped everything in the most solid darkness. So intense was the obscurity that although, from the Assaye being driven nearly on to the Zerobia, that ship was close under the bows of the Assaye, not a vestige of her lights could be perceived from the Assaye. Just before the total eclipse as the squall came, the message "Webb to Carpendale—Don't get blown into deep water" was sent, and then all signalling was at an end, and everything total darkness. Both ships "broached to" and headed in for the land, in spite of their helms being hand up. The full force of the wind came on them thus right on the beam. The awning of the Assaye was caught underneath by the wind, and bellying up in an arch nearly as high as the mizen-top, carried away with a report like a gun, snapping all the stormy and heavy iron stanchions to which the ridge-chain was secured, carrying them up right over the paying-out gear, and dashing them down on the deck, but most fortunately without doing any injury to life or limb. The break was completely buried in the wreck, but was fortunately cleared without any rope or chain getting foul round the cable or being carried into the revolving machinery, although for some time the ridge-chain was actually resting on the drum of the break, which was revolving at the rate of forty-five revolutions a minute, indicating that the ship was driving along at the rate of eight knots and a half an hour, and the cable paying out at that rate. This was a pretty good test for the mechanical arrangements, which continued to act, however, as perfectly as if the ships had only been going three knots. The wind lessened a good deal by about 8 p.m., and it became possible to speak to the Zenobia by the telegraph lamps. The first question from the Zenobia was, "Have you cast off your hawsers?" and the answer, "No, and we don't intend to." The necessary arrangements were then telegraphed from Mr. Webb, in the Assaye, to Lieutenant Carpendale for rounding the ships to, head to wind, previous to buoying the end. The first blue light from the Assaye was to indicate "Only one mile left in the ship," and the Zenobia was then to starboard her helm, and round the ships to, head to wind, so as to have the ships under command as to speed. The wind nearly all died away, however, by ten, and what little there was left had shifted to N.N.E., so that it required a very slight alteration of course to bring the ships head to wind. When about half a mile only was left, the Zenobia was signalled to ease, and then stop, and the foresail of the Assaye was dropped, so as to check the way of the ships. When nearly entirely stopped the breaks were lifted, and the break-wheel handed round by main force, so as to slacken the cable over the stern, and then the breaks were put down for a moment, and the stray-chain leading to the mushroom anchor bent on to the cable, and the anchor and buoy let go, another blue light announcing this to the Zenobia. The ship then had way given her once more, and when only a few turns were left in the hold she was again eased, so that when she finally stopped the end was close to the break. The stray-chain of the next buoy was then attached to the cable, and the end, anchor, and buoy let go in succession, a rocket from the Assaye at the same instant announcing to the Zenobia that the end was safely buoyed. A flag buoy was then let go, as the Amberwitch, which was to have done this, had parted company with the other ships in the darkness during the squall.

Thus ended the laying of the Assaye's portion of the Gwador and Kurrachee section, about 159·81 miles, leaving the end about 27 miles eastward of Osmarro. The ships then steered for Osmarro, going slowly, in order to make the bay only at daylight; and the bay was entered at 8 a.m. of the 5th of May by the Zenobia, Assaye, and Amberwitch. This was the rendezvous appointed for meeting the Semiramis, with the Cospatrick and the Sind, which ships were to bring stores from Kurrachee. The Sind arrived that same day, and during the day all spare pieces of cable were transhipped into the Amberwitch from the Assaye, and the machinery of the Assaye was pulled down and struck below.

On the 7th the Semiranis arrived at 8.30 a.m. with the Cospatrick in tow, and that day was employed in preparing the latter vessel finally for the reception of men and stores, &c. On this evening another very sudden and heavy squall, with heavy rain, was experienced. On the 9th Mr. Webb, in the Amberwitch, proceeded to sea to find the buoys on the end, it having been arranged that the Cospatrick should be brought out by the Zenobia on the following morning (the 10th), and anchored near the Amberwitch, so that the end of the submerged cable might be passed by the Amberwitch to the Cospatrick, and then spliced on to the cable in that ship. The flag buoy and buoy on the bight were found by the Amberwitch on the 9th, and the ships anchored near them; but the buoy on the end was gone. On the morning of the 10th the buoy on the bight was weighed, and the short piece between this point and the end buoyed and let go, and sufficient cable wound into the Amberwitch to veer and haul on. Meantime the Zenobia had brought out the Cospatrick, and that ship was anchored near the Amberwitch. The Amberwitch was then steamed up under the stern of the Cospatrick, paying out cable from her bow sheave as she went, and then hung

by a hawser to the Cospatrick. The end was then passed in at the stern and sheave of the Cospatrick, and the Amberwitch cast off. The joint was then attempted, but the same difficulty which has been alluded to before as having occurred when attempting to make the joint during the repairing expedition was here experienced, and it was found impossible to make a joint. The end was accordingly passed back to the Amberwitch, and "picking up" cable was commenced at 8.30 p.m. in the hope of finding some place where the gutta-percha was more docile. At 10 p.m. the Amberwitch was anchored, and picking up resumed the next morning at daylight until 11 p.m. of the 11th, when ten miles having been picked up, and the cable cut every half mile without any success, a consultation was held, when Mr. Laws suggested the following plan for overcoming the difficulties, which was employed with success. It was evident that the air which forced the warm gutta-percha into bubbles came from whatever minute spaces existed between the copper and gutta-percha, and that the air was forced up by the hydrostatic pressure acting on the submerged gutta-percha. If, therefore, the core could be choked or strangled, as it were, close to the part to be joined, so as to confine the air within the cable, the difficulty would be overcome. The plan proposed by Mr. Laws was to put two grooved clasps of wood round the core, and by binding them tightly together so as to squeeze the gutta-percha tightly against the copper conductor for a space of four or five inches. The plan was tried and answered perfectly, and an experimental joint was made to test it. The next morning (the 12th) some more cable was wound in the Amberwitch to veer and haul by, and the Cospatrick was anchored on the starboard beam, and the end once more passed on board the Cospatrick. A joint was then begun according to Mr. Laws' plan, and accomplished without any difficulty. The splice was then commenced, and at 4 p.m., all being ready, the Zenobia anchored ahead of the Cospatrick and passed hawsers. At 5 p.m. the ships got under weigh, and paying out commenced again. This proceeded throughout the night of the 12th, the ship going over the ground, when the tide was with her, at the rate of 6·27 knots an hour, the Anberwitch keeping ahead and on the bow of the Zenobia, and sounding constantly, and signalling to the Zenobia the depth. About 8 a.m. of the 13th nearly all the main cable available in the Cospatrick (eighty-six miles) was expended, and the necessary arrangements for rounding to and buoying the end telegraphed from the Cospatrick to the Zenobia. At 9 a.m., all but about a mile being expended, the Zenobia was rounded to head to wind, which was from the westward. The foresail of the Cospatrick was then dropped, and thus the vessel was completely under command. The bight was first buoyed and then the end buoyed and let go, about ten miles from the landing-place at Cape Moiree. About this time the Sind arrived from Kurrachee, having on board Sir C. Bright, who had, with Colonel Stewart, arrived at Kurrachee from Bagdad in the Coromandel the day before. The Zenobia then cast off the Cospatrick, which ship was then taken in tow by the Sind, and towed to Kurrachee; Sir C. Bright, Mr. Laws, Mr. Webb, and Mr. Woods taking passage in the Amberwitch, to complete the section by landing the shore end, and paying out cable to the end just buoyed. The Zenobia and Amberwitch then steamed to Cherna Island (an island a few miles from the proposed landing-place), and anchored under the lee of the island for the night, and during the night the shore end was coiled from the Amberwitch into the paddle-box boats.

On the morning of the 14th the Amberwitch was taken opposite the landing-place and anchored. A good bit of swell rolled into the bay, and the wind being from the westward made the beach where the end was to be landed a dead lee shore.

The two paddle-box boats, filled as usual with cable and towed by a cutter, started about 9 a.m. for the beach, paying out cable as they went. The swell at the entrance to the bay was considerable, and threatened every minute to dash the paddle-box boats against one another. This was only prevented by holding on to the telegraph cable, by the stoppers at each "send," and then slacking away at the proper instant; at last one boat was emptied and cast off, and the other was soon afterwards beached and the end safely landed.

With some difficulty all the boats were got back safe to the ships. The Amberwitch was then got under weigh, and payed out cable for four miles out, and then anchored to finish splicing up some more cable, which it was thought would be required to reach the buoys on the end buoyed from the Cospatrick.

On the 18th, at 7 a.m., paying out towards the buoys was resumed from the Amberwitch.

When the buoys were reached the Amberwitch was anchored, and the cable passed forward, and in at the bow and heave. The ship was then again got under weigh, and the buoy on the sea end picked up and the end brought on board. The final splice of all was then commenced and let go at 4 p.m., thus completing, for the present, the Persian Gulf telegraph cable.

On the 16th the Amberwitch came into Kurrachee. On the 17th a dinner was given on board the Cospatrick, at which were present Sir C. Bright, Colonel Pelly, Captain Stewart, Commander Bradshaw, R.N., Lieutenant Carpendale and lady, Lieutenant Stiffe and lady, Captain Elmslie and lady, Mr. Young, Dr. Adair, Mr. F. C. Webb, Mr. Brasher, Mr. Alexander, and many others. Colonel Stewart, having unfortunately a previous engagement, was unable to be present, and Mr. Laws, Mr. Lambert, and Mr. Woods were also unfortunately absent.

On the 18th Colonel Stewart, Sir C. Bright, Mr. Laws, and Mr. F. C. Webb, and the rest of Sir C. Bright's staff, started in the Coromandel for Bombay, where they arrived on the evening of the 20th.

On the 24th Sir C. Bright, Mr. Laws, and the rest of Sir C. Bright's staff, excepting Mr. F. C. Webb, started for England. The latter gentleman remains, on the part of the Government, in engineering charge of the line until June, 1868, and during that time it is proposed to lay a very heavy double wire shore-end cable off Bushire instead of the present separate single cable, and it is possible that the station at Mussendum may have to be shifted to some other locality, as it is feared that the extreme heat of Mussendum will be too much for the clerks employed. Colonel Stewart left by the mail on the 24th of June for Constantinople. The Cospatrick discharged all her cargo of miscellaneous cable, consisting of the Bushire heavy shore-end, and various pieces of ordinary shore-end, main cable, and experimental cable into the tank built for that purpose at Kurrachee, and arrived under sail at Kurrachee on the 16th of June, and is now the only vessel of the five sailing ships that has not been yet discharged from Government employ, the Assaye having gone out of dry dock on the 5th, and discharged from Government employ on the 6th. The Amberwitch is still at Bombay, but will shortly return to Kurrachee.

The Persian Gulf cable was commenced in February, 1863, and the whole work has therefore lasted about sixteen months.

Nothing could be more satisfactory than the way all the arrangements for laying the cable have succeeded, and in giving credit to those who have had the management of it, it should be borne in mind that no very long cables have before been successfully laid from sailing vessels in tow, although several times before the operation has been attempted; and many who are supposed to be the very best judges in such matters prophesied utter failure.

The whole work was carried out by the Government through Colonel Stewart and the civil engineers, Messrs. Bright and Clark, and naval officers appointed by him, without letting the laying of the cable by contract to large contractors, and thus the large premiums which would have been paid to contractors for taking the risk of laying has been saved at the expense of a few thousand pounds to a firm of civil engineers, who provided the whole of the staff for testing the core and superintending and testing the cable during manufacture, designing the machinery, fitting out the ships, coiling the cable on board, and finally laying it. But in addition to the actual saving to the Government, the work, there can be no doubt, has been done in a much more satisfactory manner as regards its permanence than if it had been done by contract, in which case the saving of expense to the contractors is the principle that rules the whole proceedings.

It was also remarked by all those who, as engineers or electricians, have often been engaged before on large works of this description let by contract, where the ships and all are under the contractor, that there was, during the whole work, an entire absence of all those annoying party feelings and business quarrels which have invariably taken place on the previous expeditions, where the contractors' electricians have been at loggerheads with the Government or company's electricians, and both sets of electricians have been perpetually sneering at the engineers, and *vice versâ*, while the contractor himself, setting all Government engineers and electricians at defiance, and being in his own ships, and consequently, as it were, on his own territory, manages to make everybody in general tolerably miserable and uncomfortable.

On the Persian Gulf expedition none of these disagreeables were experienced, and as all, including naval and military officers, civil engineers, and electricians pulled together with only one interest—viz., the success of the work, and acting as they did under the authority of an officer at once skilled, courteous, considerate, and patient, the whole work, though quite as arduous as any other, was rendered so free from the annoyances common to most previous expeditions that few, we think, will remember the time they were employed on the Persian Gulf cable expedition with any other feeling but that of pleasure.

HALF-YEARLY MEETING OF THE SUBMARINE TELEGRAPH COMPANY.

THE half-yearly ordinary meeting of the shareholders of the Submarine Telegraph Company (between Great Britain and the Continent of Europe), was held at the London Tavern, Bishopsgate-street, on Tuesday, for the consideration of the accounts and balance-sheet, and the report of the directors for the half-year ending 30th June last, and for the declaration of a dividend. The following directors of the company were present:—Sir James Carmichael, Bart., the chairman (who presided over the meeting), C. Saunderson, Esq., and G. Scamell, Esq.; Mr. France, engineer, and Mr. Campbell (of Messrs. Davies, Son, Campbell, and Reeves), solicitor of the company, were also present.

At one o'clock there not being a quorum present, the meeting was delayed a few minutes, until two or three shareholders were sent for to constitute a legal meeting. At length, the requisite number being present,

The CHAIRMAN called on the secretary to read the advertisement convening the meeting.

Mr. S. M. CLARE, the secretary, then read the advertisement by which the meeting was convened.

The chairman having affixed the seal of the company to the register of shareholders, the report and statement of accounts, which had been circulated amongst the proprietors, were taken as read.

The Chairman said, in moving the adoption of the report he had much pleasure in congratulating the shareholders on the improved position of their affairs since they last met together, and he thought they might consider the returns now laid before them as very satisfactory; and particularly so when it was remembered that their receipts had been earned almost entirely on their French and Belgian cables, because, unfortunately, owing to the war carried on in Schleswig and Holstein their Danish cable had not been used,—it had remained intact,—it had been treated with the utmost respect, but business on it had been suspended, and they had received almost nothing from Denmark. And from the Hanover line their receipts had been absolutely nothing. Their principal income had been derived from the Belgian and French cables. To show the rapid progress of the company he would refer to the increase in the number of messages carried on the French and Belgian cables: for the half-year ending 30th June, 1864, the number of messages transmitted was 180,000, as against 160,404 messages for the half-year ending 30th, June, 1863. That, he thought, showed a very gratifying increase. And he might go still further and say, that in the present half-year, notwithstanding the existence of the present state of things in Denmark and Hanover, they were earning in excess of the last half-year at the rate of £100 per week. (Hear, hear.) He hoped that no long time would elapse before the state of affairs in Schleswig-Holstein would be so settled that they should be able to get back their earnings from Denmark. He trusted that in a short time a government would settle down where lately there had been so much disturbance, and that to whichever party they might have to apply, whether to Prussia on one side or to another, the company should have a return of their business with Hamburg, North Germany, and Denmark. To have got an increase of business under the circumstances was, in his opinion, a very encouraging state of things. As to the new line, from near the North Foreland to nearly twenty miles out, to join the Belgian line, they were bound by the terms of the concession to lay down additional wires to Belgium whenever the Belgian government thought it beneficial to themselves and to the company to put down such additional wires. From increased business with Belgium and Vienna the Belgian Government considered it was necessary to have additional wires, and, accordingly, they called on the company last year to put down another cable, so that there should be two cables between Belgium and England, and that there should be no interruption of communication between the two countries. The directors entered into negociations with the Belgian government on the subject, pointed out to them that beyond twenty miles from the North Foreland no interruption of communication took place, or was likely to take place, and suggested to them that if the company could come to an arrangement to secure efficient communication by laying down a branch cable of about twenty miles in length, instead of putting down a second cable the whole distance, it would be unreasonable in them to ask the company to put down a second line. He went over to Belgium for the purpose of carrying on the negociations, and he was happy to say that the Belgian government met the propositions of the company in a very fair and liberal spirit. All they said was that they were desirous of keeping up their character and prestige, so that there should be no interruption of communication with the Austro-German Union. It was explained that by the plan of the company, if the main line was injured within the distance mentioned, by joining up the loop with the main line interruption of communication would be prevented, and if anything injurious happened to the loop line there would be the main line to fall back upon. The Belgian engineer, M. Vinchent, fell in with the proposition of the company, which was agreed to by all parties concerned; and at a cost of £11,000, instead of laying out £50,000 or £60,000 in the construction of a new cable, a second line of communication had been made with Belgium. And he thought the outlay would be productive, because, as the direct route would not be interrupted, they would not have, as they had occasionally to do for weeks together, to send messages round by the more circuitous route of France, by which the company was put to additional expense and the public to inconvenience by delay. He thought the arrangement which had been made was a very favourable one to the company. He had much pleasure in moving that the report and statement of accounts be received and adopted.

Mr. Hindmarsh seconded the motion.

Mr. Squire asked what was the amount paid to the Magnetic Company?

Mr. Clare, the secretary, stated that it was one-fifth on the London, and two-fifths on the provincial and Irish business.

Mr. Squire thought they were making a poor income out of their submarine wires. The Electric and International Company made a submarine cable pay 25 per cent.

The Secretary—Has that statement appeared?

Mr. Squire said that he believed that statement had been made and appeared.

A Shareholder said that the Electric and International Company made a cable pay 25 per cent. in six months.

The Chairman and the Secretary thought there must be some mistake.

Mr. Bevan thought they had good reason to congratulate the directors on the excellent manner in which they had managed the affairs of the company. The directors had had many difficulties to encounter; they had had up-hill work to undergo in the management of the affairs of the company, and they had done all they could to rescue the company out of its difficulties. It was gratifying now to find that the directors recommended the declaration of a dividend at the rate of 5 per cent. per annum; that was a gratifying circumstance, and the shareholders might look hopefully to the future, and expect in a very few years to receive a return that would amply compensate them for the money they had invested in the undertaking. He hoped that the directors would avoid all unnecessary expenditure on new lines. As the chairman explained, the expenditure of £11,000 on a branch Belgium cable proved unavoidable, as the Belgian Government appeared to have a right to demand that that expenditure should take place. But he should like to see all unnecessary expenditure avoided, and looked forward to the time when they should have a dividend, not simply of 5 per cent., but of 7½ or 10 per cent.

The motion for the adoption of the report and statement of accounts was then unanimously agreed to.

The Chairman moved—"That a dividend for the half-year ending the 30th of June, 1864, at the rate of 5 per cent. per annum, less income-tax, be declared, and that it be payable on and after the 12th of September next."

The Rev. W. Horton seconded the motion referring to the declaration of a dividend. He very much concurred in the observations of the gentleman on his right hand (Mr. Bevan) as to the encouraging aspect of the affairs of the company. He did think they had now succeeded in overcoming the most formidable difficulties they had to grapple with, and it appeared to him the prospects of the company were now brighter than he ever knew them to be before. He felt very great confidence in the wisdom with which the affairs of the company were managed, and he quite coincided in the congratulations presented to the directors that they were prepared to propose a dividend at the rate of 5 per cent. per annum.

The motion was carried unanimously.

The Chairman moved, that the retiring directors, Lord De Mauley, Samuel Gurney, Esq., M.P., and Captain Grant be re-elected.

The Rev. W. Horton seconded the motion.

Carried unanimously.

The Chairman moved, that the retiring auditors, George Copeland Capper, Esq., William Cole, Esq., and Mr. Alderman Dakin, be re-elected.

The motion was seconded by Mr. Hindmarsh, and agreed to.

A vote of thanks having been accorded to the chairman, the meeting broke up.

HALF-YEARLY MEETING OF THE UNIVERSAL PRIVATE TELEGRAPH COMPANY.

A General Meeting of the shareholders of this company was held at the offices, Adelaide-street, West Strand, on Wednesday afternoon, to consider a recommendation of the directors to declare a dividend for the half-year ending 30th June last, at the rate of six per cent. per annum.

Jonathan Mellor, Esq., of Rochdale, chairman of the board of directors, presided.

The Secretary read the following circular, a copy of which had been sent to every shareholder:—

"Universal Private Telegraph Company,
4, Adelaide-street, West Strand, W.C.,
London, August, 18th, 1864.

"Sir,—Although the special Act of this company only requires that one general meeting of shareholders shall be held annually, the directors, after a careful review of the progress of the works and the profits already realised, have issued summonses for an extraordinary general meeting, to be held at this office, at 2 o'clock, p.m., on the 24th inst., for the purpose of deciding whether an interim dividend for the half-year to 30th June, at the rate of six per cent. per annum, shall be declared.

"I am happy to inform you that after payment of this dividend there will remain £2,373. 16*s*. 5*d*. to the credit of revenue, being £320. 17*s*. 4*d*. more than the balance carried forward in March last, and there appears to be every prospect of maintaining this dividend for the future.

"The question of the honorarium to be awarded to the directors, which would have been introduced at the last general meeting but for a casual oversight, will be brought forward upon this occasion. This, I need scarcely say, is entirely a shareholders' question. Yours faithfully,

"Jonathan Mellor, Chairman."

The Chairman said the directors had thought it their duty to call the shareholders together for the purpose of recommending them to declare an interim dividend for the half-year, at the rate of six per cent. per annum. They could recommend this with confidence, which would show the shareholders that considerable attention had been bestowed upon the management of their affairs, the results of which gave promise of an increased dividend in the future. They would see from the accounts which they had received that the directors had not touched the balance, which was carried over from the last meeting, and the proprietors would receive the dividend proposed to be declared leaving that balance intact. There was another question to be brought before them that day, and that was the subject of a honorarium to the directors, which, but for a casual oversight, would have been brought forward at the last meeting. That, of course, was a question for the consideration of the shareholders. He moved that a dividend be declared for the half-year ending 30th June last, at the rate of five per cent. per annum.

Mr. Gaussen, deputy-chairman, seconded the motion, which was carried unanimously.

Mr. Mackenzie said the shareholders had had the benefit of the services

of the directors some years for nothing, and he thought it was high time they made them some acknowledgment for those services, which had been of a most valuable character. He did not know exactly what to propose or what the directors would be satisfied with, but he thought that they ought to be paid from the commencement.

The Chairman said the directors did not wish the motion to have a retrospective action, but simply to take effect from the present year.

Mr. Mackenzie said he would rather have a small and efficient board handsomely paid, than a large board badly paid. There was no question that they ought to pay their directors handsomely. He considered that the position of the Company was very much better now than it was two or three years ago, and the benefits conferred upon the public by the company were such that its progress would go on increasing every year. It was like the supply of gas, to talk of cutting it off would not suit the public; there was only a sort of Hobson's choice about it, and they must go on with it, as they could not do without it. A similar result would follow if it was proposed that the Private Telegraph Company should shut up shop. The public could not dispense with its services; and every one they supplied with the telegraph would recommend his friends to be similarly supplied. He was satisfied that though their dividend was now six per cent. per annum, it would, in the course of a few years, be greatly increased. As to the honorarium to the directors, he thought, considering they had the services of gentlemen from Glasgow, Manchester, and London, in the management of the company, that the sum he was about to propose was not too large. He had great pleasure in proposing that a sum at the rate of £600 per annum be awarded to the directors for their services.

Mr. Reid had great pleasure in seconding the motion.

A Shareholder made some observations, but they were wholly inaudible at the inconvenient spot set apart for the representatives of the press.

Another Shareholder thought that the expenses of directors living out of London, consequent upon their attending board meetings, should be defrayed out of the funds of the company, and suggested that such an addition be made to the motion.

The mover and seconder having acquiesced, the motion was with the addition carried unanimously.

The Chairman, in acknowledging the vote, thanked the shareholders for the confidence they reposed in the directors, which would be a stimulant to greater exertions on their part. He would rather have their actions speak for them than formal addresses delivered at meetings of shareholders.

Mr. Mackenzie moved a vote of thanks to the chairman, deputy-chairman, and directors, for their assiduity and great attention to the interests of the shareholders. He spoke from experience when he said that the directors, individually and collectively, gave their personal attention to the business of the company, and that was the secret of their success.

The motion was seconded, and carried unanimously.

The Chairman, in returning thanks, said every diligence and attention should be given by the directors to the interests of the company, in order that it might be made that satisfactory concern which he thought it was capable of being. The directors were assisted by zealous officers who did all they could to promote the interests of the company, and to make it what the directors wished it to be—profitable to the shareholders.

The meeting then separated.

CORRESPONDENCE.

THE SUBMERSION OF DEEP-SEA TELEGRAPH CABLES.

To the Editor of the Telegraphic Journal.

Sir,—I beg herewith to forward to you, for Mr. Martin's perusal, the pamphlet descriptive of the cylinder which I have proposed for and still believe to be the best means of laying submarine cables. Your correspondent is perfectly correct as to Mr. Lavater's prior specification of a floating cylinder, but without any means of preventing the cable, once partially unrolled, from running itself off entirely in deep water, or of regulating the delivery of cable in proportion to the rate of the ship. This is accomplished by the putting of paddle-wheels on the ends of the cylinder in my system.
